CHANGES IN RENAL CONCENTRATING ABILITY PRODUCED 
BY PARATHYROID EXTRACT *

BY FRANKLIN H. EPSTEIN,† DAVID BECK,‡ FRANK A. CARONE,|| HOWARD

(Submitted for publication February 18, 1959; accepted March 20, 1959)

Polyuria is a frequent symptom of hyperparathyroidism. Impairment of renal concentrating ability, often out of proportion to other signs of renal insufficiency, has been noted in patients with hyperparathyroidism (1–3) as well as in patients and animals with hypercalcemia due to other causes (4–6). In many patients with hyperparathyroidism, extensive deposits of calcium in the renal parenchyma, secondary fibrosis, superimposed pyelonephritis and vascular disease have combined to destroy considerable amounts of renal substance. The mechanism of the reported decrease in renal concentrating ability in such patients is not clear, since fixation of urinary specific gravity is a well-known accompaniment of the simple ablation of renal tissue (7).

In the present experiments, renal concentrating capacity was found to be depressed in dogs in which hypercalcemia had been induced for only 24 hours by injecting parathyroid extract. This functional defect was associated with morphologic changes in the distal portions of nephrons and the collecting ducts.

MATERIALS AND METHODS

Mature female dogs weighing 8 to 22 Kg. were maintained on Purina Chow® supplemented with horsemeat. All experiments were carried out under light pentobarbital anesthesia. Inulin was determined by the method of Walser, Davidson and Orloff (8), osmolality of serum and urine with a Fiske osmometer, serum calcium according to Kingsley and Robnett (9), and sodium in serum and urine by flame photometry.

Group I. Studies of concentrating ability during graded osmotic diuresis

Four dogs were studied. Prior to the experiment, food and water were withheld for 24 hours. Five units of vasopressin in oil¹ was injected subcutaneously on the evening before the experiment. A control study was carried out on each dog one week before it received parathyroid extract. A total of 90 units of parathyroid extract ² per Kg. was injected subcutaneously in three divided doses during the 24 hours preceding the second study. During the experiment, 0.5 per cent inulin in physiological saline was infused at a rate of 1 to 1.5 ml. per minute, together with 50 to 100 milliliters of vasopressin ³ per Kg. per hour. Samples of urine and blood were collected at 10 to 15 minute intervals. After a suitable period of equilibration, urine flow was slowly increased from less than 1 ml. per minute to more than 10 ml. per minute by gradually increasing the rate of infusion of 5 per cent mannitol in 0.72 per cent saline. This technique permitted examination of the concentrating function over a wide range of urine flows and rates of solute excretion.

Group II. Studies of concentrating ability during a constant infusion of mannitol

Seven dogs were studied before and after receiving parathyroid extract in doses comparable to those given to the preceding group. Five per cent mannitol in 0.72 per cent saline was infused at a rate of 0.50 to 0.75 ml. per Kg. per minute throughout the experiment. Inulin and vasopressin were infused simultaneously as in Group I. Following an equilibration period of one hour, when urine flow had reached a constant value, collections of urine were made every 10 to 15 minutes. Samples of blood were obtained from the jugular vein at intervals of 20 to 30 minutes. Three dogs were restudied in the same way at intervals up to five weeks after treatment with hormone.

In six additional dogs not given parathyroid extract, the effect of progressive osmotic loading on T³H₂O was studied by increasing the rate of infusion of 5 per cent

1214
mannitol in saline stepwise to three or four times the initial rate of 0.50 to 0.75 ml. per Kg. per minute.

Dogs were autopsied at intervals up to two months after receiving parathyroid extract. The kidneys were fixed in formalin and studied by microdissection as well as by standard histological techniques.

RESULTS

Subcutaneous injection of 60 to 97 units of parathyroid extract per Kg. over a period of 24 hours resulted in an increase in serum calcium to 15 to 20 mg. per 100 ml. During this time the animals usually looked sick and listless and exhibited polyuria. Serum calcium returned to normal after 48 to 72 hours and the dogs had generally regained their usual vigor by one week after injections of parathyroid extract were discontinued.

Glomerular filtration rate (GFR) usually decreased, but remained essentially unchanged in two dogs and rose in one animal, following the administration of parathyroid extract.

The maximum urinary concentration rate \( \frac{U_{\text{osm}}}{P_{\text{osm}}} \) achieved before mannitol loading in dehydrated dogs injected with vasopressin in oil was considerably diminished following parathyroid extract (Figure 1) but tended to rise to or toward the control level several days to weeks after the serum calcium had fallen to normal.

Studies of concentrating ability during graded osmotic diuresis (Group 1) demonstrated impairment of water conservation at all levels of urine flow and solute load. The four experiments of this group are summarized in Figures 2A through 2D. Despite the continuous infusion of large amounts of exogenous vasopressin, urine became hypotonic to plasma at relatively low levels of solute excretion in three out of four experiments and the excretion of free water increased thereafter with increasing solute diuresis.

Similar changes in \( T^2H_2O \) were observed in the experiments of Group II (Figure 3, Table 1). Hypotonic urine was excreted during moderate mannitol loading in five of seven dogs. Solute loads of much greater magnitude in proportion to GFR did not suffice to produce hypotonic urine in six normal dogs infused rapidly with 5 per cent mannitol in 0.72 per cent saline (Figure 4).

In experiments of Group I and Group II, the ratio of urinary sodium to total urinary solutes was not consistently altered by parathyroid extract.

Lower doses of parathyroid extract (30 to 35 units per Kg.) produced elevations of serum calcium of only 1 to 2 mg. per 100 ml. in two dogs, with no changes in renal concentrating ability or glomerular filtration rate.

The subcutaneous injection of 4.5 to 7.0 Gm. of calcium as calcium acetate into three animals resulted in increased urinary excretion of calcium. Serum calcium levels were slightly elevated two to four hours after the injection but had returned to normal by the following day. At this time \( T^2H_2O \) was found to be unaltered.

Morphological changes

Dogs autopsied within a few days after receiving parathyroid extract had focal tubular lesions of irregular patchy distribution. These were demonstrated by microdissection to lie along the ascending limbs of Henle's loop, the distal convolutions and the collecting system. They consisted of foci of hydropic swelling of the tubular epithelial cells, acute necrosis of the epithelium, frequently with calcification, and often calcification of basement membranes. The necrotic, calcifi-

Fig. 2. Impairment of T\textsuperscript{4}H\textsubscript{2}O after treatment with parathyroid extract (PTE)

The heavy diagonal line is the isotonic parameter. Points above this line represent urines more concentrated than plasma; points below the line, urines hypotonic to plasma. Note that after administration of parathyroid extract (black dots), urine became progressively more hypotonic with increasing mannitol diuresis, despite a constant intravenous infusion of vasopressin. In D note that after parathyroid extract, concentrating ability was diminished, but urine hypotonic to plasma was not produced even during heavy osmotic diuresis. It is noteworthy that this dog had the most severe impairment in glomerular filtration of all four animals in Group I.

fied, cellular debris formed obstructing casts with dilatation proximally.

In the kidneys of dogs autopsied two weeks to two months after receiving parathyroid extract there was "fatty change" of the tubular epithelium similar in distribution to the early alterations. Proliferative lesions, seen only in the medullary portion of the collecting system, consisted of intratubular cellular masses, often calcified, which produced obstruction and proximal dilatation, and
in places extended beyond the tubular basement membrane into the connective tissue stroma.

Chemical analysis of the kidneys in two instances (Table II) demonstrated an increased calcium content of the renal medulla. The amount of calcium in the renal cortex was not greatly altered by injections of parathyroid extract.

These changes will be described more fully elsewhere (13). The character and distribution of the renal lesions resembled those observed in rats intoxicated with vitamin D (6).

**DISCUSSION**

Renal function is often impaired in hyperparathyroidism (14) and although renal insufficiency may prove reversible (3, 14, 15) it frequently progresses even after the concentration of calcium in the serum is restored to normal by parathyroidectomy. Edvall (14) found the clearances of inulin and para-aminohippurate (PAH) as well as $T_M$PAH to be depressed in most but not all patients with hyperparathyroidism. Hellström (2) noted that patients with this disease frequently excreted urine with maximum specific gravity below normal, even when azotemia was absent. After operation, the ability to concentrate the urine was often restored. Cohen, Fitzgerald, Fourman, Griffiths and deWardener recorded maximum urinary concentrations below the concentration of solutes in plasma in two patients with hyperparathyroidism who in addition had reduced levels of glomerular filtration rate and (in one) a decreased renal plasma flow (3).

The present experiments suggest that the ability of the kidneys to produce a concentrated urine was impaired after only 24 hours of hypercalcemia produced by injections of parathyroid extract. Interpretation of the data is complicated by the fact that in most cases glomerular filtration rate,
was also reduced by parathyroid extract. *Acute* reductions in glomerular filtration rate, induced by compressing the renal artery of dogs undergoing mannitol diuresis, result in a rise, rather than a fall, in maximum urinary osmolality (16). Nonspecific destruction of renal tissue, whether produced by injecting an aminonucleoside into the renal artery, by experimental pyelonephritis or by temporary renal ischemia, does not appreciably reduce the ratio of T^4H_2O to glomerular filtration rate, even though the latter may be considerably depressed (17). This is also true, in general, of patients with chronic nephritis whose glomerular filtration rate is below normal (18). By contrast, when concentrating capacity (T^4H_2O) was referred to GFR in the present experiments, a considerable difference between normal dogs and those treated with parathyroid extract was apparent. Finally, in two dogs of the present series (3 and 4, Table II) T^4H_2O diminished after parathyroid extract without a concomitant decrease in glomerular filtration rate.

Although a progressive increase in the quantity of solute excreted by each nephron may, under some circumstances, result in the excretion of a dilute urine (19) it seems unlikely that such an increase in solute load was responsible for the present results. Massive solute diuresis in normal dogs did not lower T^4H_2O to the degree observed in animals treated with parathyroid extract. Hypercalcemic dogs of Group I infused with vasopressin produced a hypotonic urine while excreting the same amount of solute per unit of GFR as they had done when they were normal and able to concentrate the urine. Mere destruction of nephron units or an overall decrease in the rate of glomerular filtration could not, therefore, have been primarily responsible for the diminution in concentrating capacity which was observed.

The morphological alterations in these kidneys, localized chiefly to the ascending portion of Henle's loop, the distal convoluted tubule and the collecting ducts, are interesting in the light of current theories concerning the mechanism by which the kidneys reabsorb water and excrete a concentrated urine (20, 21). Impairment of renal concentrating ability might theoretically result from: 1) a decrease in the reabsorption of sodium without water in the ascending limb of the loop of Henle, 2) disruption of the counter-current mechanism by which sodium (and urea) are concentrated in the medulla, and 3) slowing of the back-diffusion of water from the collecting ducts to the hypertonic interstitial fluid of the renal medulla (a process normally facilitated by vasopressin). The data of these experiments are probably compatible with any of the above explanations, although excretion of hypotonic urine by hypercal-
cemic dogs infused with vasopressin implies the continued active reabsorption of sodium without water in distal portions of the nephron.

The changes in concentrating ability observed in these experiments were associated with an elevated serum calcium, yet it is noteworthy that hypercalcemia of the same degree produced acutely by infusions of calcium salts does not result in nearly as large changes in T\(^{3}H\)\(\text{O}\) as those observed here (22). Perhaps the serum level of calcium is less important in this regard than the calcium content of cells lining the medullary tubules, or the structural and metabolic changes induced in the renal medulla by prolonged hypercalcemia and/or hypercalciuria. In addition to producing hypercalciemia, parathyroid hormone probably directly induces certain changes in the metabolism of renal tissue (23) which are not entirely reproduced by increasing the concentration of calcium in the serum, the renal cells, or the urine. It is of interest that morphological and functional changes in the kidneys similar to those of the present experiments can be produced by the administration of large doses of vitamin D to rats (6). The frequent association of polyuria with hypercalcemia and nephrocalcinosis of diverse origins lends support to the thesis that changes in calcium metabolism are at least partially responsible for the hypostenuria of hyperparathyroidism.

**SUMMARY**

1. The effects of parathyroid extract upon renal function and structure were studied in dogs.

2. After 24 hours of hypercalcemia induced by parathyroid extract, glomerular filtration rate was usually but not always decreased.

3. Renal concentrating capacity, as measured by the maximum solute concentration of urine during dehydration and by T\(^{3}H\)\(\text{O}\) during mannitol diuresis, was severely impaired. Dogs treated with parathyroid extract excreted a hypotonic urine during moderate mannitol diuresis despite the infusion of large amounts of exogenous vasopressin.

4. These changes were associated with morphological alterations demonstrated by microdissection to lie chiefly in the distal portion of the nephron and the collecting ducts.
