Secretion of Glucagon from the Isolated, Perfused Canine Pancreas

JOHAN IVERSEN

From the Second University Clinic of Internal Medicine, Kommunehospitalet, Århus, Denmark

ABSTRACT Using the isolated, perfused canine pancreas preparation, previously described, the interrelation of the secretion of pancreatic glucagon and insulin was studied after stimulation with glucose, gastrointestinal hormones, and the amino acid arginine.

The results confirm the concept that pancreatic glucagon is a hormone of "glucose need" and suggest that it may be important in a moment to moment control of glucoregulation. The secretion of pancreatic glucagon was stimulated after infusion of gastrin, pancreozymin, and arginine, while no increase was associated with secretin infusion. The magnitude of the increase was closely related to the glucose concentration present in the perfusion medium, being higher and more pronounced during perfusion with low concentrations of glucose (25 mg/100 ml or 50 mg/100 ml).

Stimulation of insulin secretion was seen after glucose, gastrin, pancreozymin, secretin, and arginine. The magnitude of the increase was again closely related to the glucose concentration present, this time being higher and more pronounced during perfusion with high glucose concentrations (150 mg/100 ml).

Secretion of both pancreatic hormones always followed a biphasic response pattern after the stimuli mentioned, similar to the characteristic release pattern previously described for insulin after an increment in glucose concentration.

In order to elucidate whether endogenous pancreatic glucagon possesses an insulinogenic action, as it has been shown to be the case with the administration of exogenous pancreatic glucagon, the time interrelationship of the secretion of pancreatic glucagon and insulin was investigated by determining the initial rise of the hormones after stimulation with gastrin, pancreozymin, and arginine. The rise of glucagon and insulin occurred simultaneously, i.e. inside a 10 sec period. This does not, however, exclude with certainty an insulinogenic role of pancreatic glucagon.

INTRODUCTION

Studies on the physiological role of pancreatic glucagon have been carried out by determining the glucagon concentration in peripheral plasma in humans after administration of various substances (1-3). The interpretations of the results of immunoassayable plasma-glucagon determinations, however, have been difficult and questionable for a number of reasons.

First of all, any response observed in vivo must be the result of the effect of the substance itself as well as a number of known and unknown counterregulatory mechanisms of nervous and humoral origin. Second, it is implied that pancreatic glucagon is diluted in peripheral blood to concentrations near the limits of the sensitivity of most immunoassays. Third, more or less specific antibodies must be employed to distinguish these low values of pancreatic glucagon from other immunoreactive substances in plasma (3-4). Catheterization studies on the pancreaticoduodenal vein glucagon in dog (5-10) have yielded important information on the secretion of pancreatic glucagon. Even such experiments, however, give results which in some cases may be difficult to interpret mainly because the experimental set-up precludes control and measurement of the pancreatic blood flow, and because up to 90% of the glucagon immunoreactivity estimated in the pancreaticoduodenal vein with unspecific antisera consists of other substances (gastrointestinal factors, proteins, etc.) (4, 11, 12). This renders difficult the detection of small acute (though possibly physiologically important) changes in the secretion of pancreatic glucagon.

In the present study, the secretion of pancreatic glucagon has been investigated using the effluent from the isolated, perfused canine pancreas. The purpose of the study was to provide in vitro information on the re-
of the perfusion; both parameters are constant throughout the experiment. Leakage from the preparation is negligible, most often it is zero. Edema never occurs during the experimental period of 4-6 hr.

To assess the viability of the organ, glucose uptake, oxygen consumption (for details, see (13)), potassium concentration, and lactate production were measured. They were constant throughout the experiment and gave some indication of the status of the preparation as a whole. The definitive assessment of the islet function was made by observing the insulin response to glucose at the end of each experiment.

Biochemical methods. Glucagon and insulin were measured by radioimmunoassay using the wick-chromatography method described by Ørskov (14, 15). This single antibody assay is well suited as it allows for an easy determination of "incubation" damage. Such an estimation is theoretically especially important on the effluent from an organ which produces proteolytic enzymes. There was no interference in the immunological system of either the 0.2% albumin or the 4% Macrodex concentration. Still, the precaution was taken to use the perfusion buffer as solvent for the standard to create identical media.

The system for glucagon measurement employs labeled beef glucagon prepared according to Hunter and Goodwood (16). After addition of bovine albumin and Trasylopl (10,000 KIU/ml Fa. Bayer, Leverkusen, Germany) to produce final concentrations of 1% and 500 KIU/ml, the crude iodination product was dialyzed (VisKing tube 28/48, Union Carbide Corp, New York) against an anion exchange resin (Amberlite IRA 401, Rohm and Haas Co, Philadelphia) at 4°C for 3/4 hr × 2. The glucagon-125I was purified by means of a column of Sephadex (Pharmacia, Uppsala, Sweden) (mixture of G-50 fine and G-75 superfine in the ratio 5:1) using as solvent a phosphate buffer (0.04 M, pH 8.0) containing merthiolate (0.6 M), bovine albumin (10 g/liter), and Trasylopl (500 KIU/ml). After purification, the glucagon-125I contained about 1-3% of damaged material, estimated as nonspecific migration of the labeled hormone. Antigliucagon was produced by immunization of rabbits with twice recrystallized porcine glucagon (Novo A/S, Copenhagen, Denmark). Beef glucagon was used as a standard as canine standards were not available. However, canine pancreatic glucagon appears to be immunologically similar to beef glucagon (17). Trasylopl was added to the labeled hormone in a concentration of 500 KIU/ml to protect glucagon against degradation. 50 μl standards (triplicate) or samples (single determinations of the 400-600 samples) were pipetted into 10 × 50 mm tubes. For more exact determination of extremely low glucagon values 50 μl standards or samples were employed (see Fig. 1). 100 μl porcine glucagon-125I and 100 μl antitbeef-glucagon serum were added. After 24 hr of incubation at 4°C a 200 μl sample of the mixture was applied to the wick (Whatman 3 MM). When 500 μl standards or sample were used the incubation period was prolonged to 48 hr, and a 230 μl sample of the mixture was applied to the wick. Every 12th tube contained 100 μl buffer instead of anti-glucagon serum for check and calculation of damage. With the more sensitive assay it is possible to distinguish differences in glucagon concentrations of 10 pg/ml with 95% confidence (0 pg/ml standards, n = 6, 10 pg/ml standards, n = 3).

The antigliucagon employed does not distinguish between glucagon from the gut (GLI) and glucagon from the pancreas. However, the present preparation consists only of the pancreas and the proximal 10 cm of the attached duodenum.
which contains very little glucagon-like immunoreactivity (6, 18, 19).

A slight modification was introduced in the system employed for insulin measurements. The modifications are as follows: (a) Porcine insulin standards (porcine insulin being structurally and immunologically identical to canine insulin) were prepared in the perfusion buffer, containing 0.2% bovine albumin (Ortho) and 4% dextran (Macrodex). 15 µl standards (triplicate) or samples (single determinations) were pipetted into 10 X 50 mm tubes. In experiments where high insulin concentrations (≥1000 µU/ml) were encountered, a modified assay was set up with 5 µl standards or samples. (b) 100 µl human insulin-125I and (c) 100 µl anti-human insulin serum were added, and after 24 hr of incubation at 4°C, a 180 µl sample of the mixture was applied to the wick. As in the glucagon immunoassay check and calculation of "incubation" damage were carried out by substituting anti-insulin serum with buffer in every 12th tube.

No proteolytic enzymes escaped from the perfused pancreas. This was apparent from the fact that perfusate incubation damage was identical to that calculated for the standard media both estimated chromatographically as the nonspecific migration of labeled hormone with plasma proteins and immunologically as the maximum binding of labeled hormone in the presence of an antibody excess. The values of nonspecific migration have varied between 4 and 12% depending upon the storage time of the labeled hormone. Maximum binding of the labeled hormone in the presence of an antibody excess corrected for nonspecific migration varied between 82-90% in the glucagon assay, depending upon the quality of the labeled hormone. For the insulin assay values of 92-96% were obtained.

Glucose was measured using a glucose oxidase method (Glox, Kabi reagents, Stockholm, Sweden). There was no interference from the high dextran concentrations in these glucose determinations.

Experimental procedure. Samples were taken every minute from the influx and the efflux. To protect glucagon against proteolytic degradation, 250 µl EDTA (30%) was added to the tubes collecting the efflux, resulting in a final concentration of 4 mg/ml. The samples were transferred within ½ hr to a freezer providing a temperature of -20°C.

The substances to be examined were added to the perfusate by means of constant infusion syringes, containing appropriate high concentrations. The infusion pumps were adjusted to speeds which gave from 0.1 to 0.56 ml/min to the flow which was 18–20 ml/min. When any of the hormones was administered it was dissolved in the perfusion buffer immediately before use.

Synthetic human gastrin I was obtained from ICI (Imperial Chemical Industries Limited, Pharmaceuticals Division, Cheshire, England). Porcine pancreozymin, containing

approximately 12.5 Crick-Harper-Raper\textsuperscript{1} units/µg and porcine secretin, containing 20 clinical units/µg were prepared and assayed by Professor E. Jorpes and Dr. V. Mutt of Karolinska Institutet, Stockholm. During stimulation with gastrin, pancreozymin, and secretin, samples from the inflow were measured for glucagon and insulin in order to correct for impurities of the gut-hormone preparations used, and also because the presence of glucagon-like immunoreactivity might play a role in the rise in insulin secretion observed. None of the intestinal hormones, in the concentrations in which they were used in these experiments, contained glucagon-like immunoreactivity which could be detected by our glucagon immunoassay. Likewise, no insulin immunoreactivity was detectable.

Arginine was given as L-arginine hydrochloride. There was no effect upon the standard immunoassay curve for glucagon and insulin by arginine.

The pancreas was perfused for an equilibration period of 30–40 min with a glucose concentration of 25 mg/100 ml or 50 mg/100 ml.

The insulin and glucagon response to glucose concentrations of 25, 50, 150, and 350 mg/100 ml was investigated. The effect of gastrin, pancreozymin, and secretin as well as that of the amino acid arginine was investigated at low (25 or 50 mg/100 ml) concentrations of glucose and at a glucose concentration of 150 mg/100 ml in the perfusate. To ensure that the response seen after one stimulus was not affected by the prior treatment of the pancreas, the order of stimulation and changes of glucose were reversed. At the end of each experiment, the insulin response to a glucose concentration of 350 mg/100 ml was checked in order to prove that the beta cells were still capable of the characteristic biphasic insulin response.

**RESULTS**

**Effect of different concentrations of glucose in the perfusate upon secretion of glucagon and insulin.** In six perfusion experiments with glucose concentrations of 25 mg/100 ml or 50 mg/100 ml in the perfusing medium, a mean glucagon concentration in the efflux of 0.46 ng/ml (\(\text{SEM} \pm 0.09\)) was obtained (Figs. 2–4 and Table 1). The insulin concentration at this concentration of glucose was 10–25 µU/ml. The sudden increase in the glucose concentration in the perfusing medium to 150 mg/100 ml immediately suppressed the glucagon output to a mean value of 0.16 ng/ml (\(\text{SEM} \pm 0.04\)). Glucose concentrations of 150 mg/100 ml elicited the well-known pattern of insulin release, a prompt rise in insulin during

**Figure 4** Effect of pancreozymin, secretin, and gastrin upon the secretion of pancreatic glucagon and insulin during perfusion with a glucose concentration of 25 mg/100 ml and 150 mg/100 ml. ▲, 1672 μU/ml peak value; >, 1200, 2248 μU/ml; >>, 5154, 3992, 2824, 1888, 2792, 2968, 3032, 2528, 3000 μU/ml; >>, 2248, 1584, 1248, 1032, 1160, 1040, 1104, 1336 μU/ml.
approximately 2–3 min which was followed by a rapid decline leveling off to values of about half the peak value. By changing the glucose concentration in the perfusate back to 25 mg/100 ml or 50 mg/100 ml the mean glucagon concentration again rose within 1 or 2 min to levels characteristic of low glucose concentrations 0.39 ng/ml (SEM ±0.07) and insulin returned to low values. These changes in the secretion of glucagon and insulin could be repeatedly shown after alterations in perfusate glucose throughout the experiment in most of the experiments. In experiments where the pancreas was perfused with a low glucose concentration for 2–3 hr before the glucagon concentration was increased to 150 mg/100 ml and where it had been intensively stimulated with gastrin and pancreozymin, the inhibition of glucagon secretion following change in glucose appeared less obvious and was in some instances absent. At the end of each experiment, the glucose concentration was increased to 350 mg/100 ml. At this glucose concentration glucagon secretion was not further inhibited (see Discussion). This high glucose concentration always elicited the normal biphasic insulin response to an increment in glucose.

Effects of gastrin, pancreozymin, and secretin during perfusion with glucose concentrations of 25, 50, and 150 mg/100 ml. Stimulation of glucagon secretion was obtained in each of 4 perfusion experiments with an infusion of gastrin (65 ng/ml for 8 min) and in each of 10 perfusion experiments with an infusion of pancreozymin (1.5 U/ml for 6–8 min), while stimulation was not observed after an infusion of secretin (0.35 U/ml for 5–8 min) in any of 6 perfusion experiments. Representative experiments of these different stimulations are shown in Figs. 2–5.

The stimulatory effect of gastrin and pancreozymin on glucagon secretion was most pronounced during perfusion with the lower glucose concentration in the perfusate. The mean glucagon level after a gastrin infusion rose from 0.19 ng/ml (SEM ±0.06) to a peak of 3.72 ng/ml (SEM ±0.02) at 2 min; after a pancreozymin infusion it rose from 0.36 ng/ml (SEM ±0.07) to a peak of 4.59 ng/ml (SEM ±1.11). However, increases in glucagon secretion were also observed at a glucagon concentration of 150 ng/100 ml, which by itself effectively inhibits glucagon secretion. Thus the mean glucagon level after gastrin rose from 0.15 ng/ml (SEM

Figure 5 Effect of pancreozymin, secretin, and gastrin upon the secretion of pancreatic glucagon and insulin during perfusion with a glucose concentration of 25 mg/100 ml and 150 mg/100 ml. □, peak value 1672 μU/ml; □□□, 2922, 2240, 1152, 1216, 1000, 1216, 1608, 1160 μU/ml; □□□, 1496, 1692 μU/ml; □□□, 2041, 1556 μU/ml.
The secretion of glucagon in isolated, perfused canine pancreas was studied. Inhibition of a rapid rise in plasma glucose concentration after administration of arginine (n = 8), secretin (n = 6), and pancreozymin (n = 10) during perfusion of gastrin was noted. The increased insulin output observed after these stimuli showed the characteristic biphasic response pattern previously described after an increment in glucose (20, 21). The stimulatory effect of the intestinal hormones was not consistently present during perfusion with a glucose concentration of 25 mg/100 ml. However, in three experiments, which were carried out at a glucose concentration of 50 mg/100 ml an effect was always observed. The difference in insulin response after pancreozymin at different glucose concentrations was not significant. The secretion of glucagon from the isolated, perfused canine pancreas showed a biphasic release pattern similar to that described for insulin.

In contradistinction an instantaneous very large increase in insulin secretion always occurred after an infusion of gastrin, pancreozymin, or secretin during perfusion with a glucose concentration of 150 mg/100 ml. The mean insulin level after gastrin infusion rose from 264.0 μU/ml (SEM ±61.2) to a peak of 2000 μU/ml (SEM ±126.3); after pancreozymin it rose from 428.5 μU/ml (SEM ±81.3) to a peak of 3551 μU/ml (SEM ±452.5) and after secretin it rose from 253.0 μU/ml (SEM ±59.6) to a peak of 2187 μU/ml (SEM ±520.4). All the peaks occurred at 2 min. The increased insulin output after these stimuli showed the characteristic biphasic response pattern, previously described after an increment in glucose (20, 21). The stimulatory effect of the intestinal hormones was not consistently present during perfusion with a glucose concentration of 25 mg/100 ml. ** P, values using Student’s t test.

concentrations can be seen in Figs. 2 and 3. The mean results are recorded in Tables II–IV. In Fig. 6 the mean results of the stimulation periods from the different perfusion experiments are depicted.

A representative experiment of reversing the order of stimulation and change of glucose is given in Figs. 4 and 5. As will be seen the same glucose dependence was obtained.

Effect of arginine during perfusion with a glucose concentration of 25, 50, and 150 mg/100 ml. The effect of infusion of arginine (4.3 mm for 10 min) on glucagon output was studied in nine perfusion experiments, at low glucose concentrations as well as at the high concentration of glucose which effectively inhibits glucagon secretion in our experiments. The mean glucagon level rose during perfusion with a glucose concentration of 25 mg/100 ml from 0.25 ng/ml (SEM ± 0.01) to a peak of 2.60 ng/ml (SEM ± 0.61) at 2 min; during perfusion with a glucose concentration of 150 mg/100 ml it rose from 0.15 ng/ml (SEM ± 0.03) to a peak of 1.63 ng/ml (SEM ± 0.34) at 2 min. The pattern of response was biphasic, identical to that seen after

Stimulation with gastrin and pancreozymin and again the response was most pronounced during perfusion with a low glucose concentration of 25 mg/100 ml or 50 mg/100 ml (Figs. 2 and 3).

No rise in insulin secretion occurred after an infusion of arginine during perfusion with a glucose concentration of 25 mg/100 ml (Fig. 2) while a consistent, although small increase in insulin was seen during perfusion with the slightly higher glucose concentration of 50 mg/100 ml (Fig. 3). At 150 mg/100 ml of glucose in the perfusate a biphasic, instantaneous and large increase in insulin secretion was observed (Figs. 2 and 3). The mean insulin level rose from 314.7 μU/ml (SEM ±50.9) to a peak at 2 min of 2271 μU/ml (SEM ±420). After termination of the infusion there was a rather pronounced fall of insulin followed by a second rise back to prestimulation levels. The mean results are condensed in Table V. In Fig. 6 the mean results of the stimulation periods from the different perfusion experiments are depicted.

creozymin, and arginine. The response of glucagon and insulin to gastrin, pancreozymin and to arginine infusion occurred simultaneously during perfusion with a glucose concentration of 25, 50, and 150 mg/100 ml. In these studies, effluent samples were collected at 5 sec intervals during the first 2 min after addition of stimulus. The first detectable rise in glucagon and insulin occurred in the same 5 sec sample in five experiments, or in consecutive samples where the insulin rise preceded the glucagon rise in five experiments, and glucagon preceded insulin in seven experiments. In the experiments where the rise in glucagon and insulin did not occur in the same 5 sec sample the first detectable rise occurred for that hormone which showed the greatest relative rise after stimulations. Insulin thus preferentially preceded glucagon at high glucose concentrations, while the opposite time pattern of secretion was found at low glucose concentrations. The delay before the initial rise coincides in the present in vitro preparation with the time it takes for the stimulus to reach the islets of Langerhans. Fig. 7 shows representative situations of the time interrelationship of the secretion of glucagon and insulin in three different perfusion experiments during perfusion with a glucose concentration of 150 mg/100 ml.

DISCUSSION

In the present investigation results are reported on the secretion of pancreatic glucagon from the isolated, perfused canine pancreas.

In vitro studies on the secretion of pancreatic glucagon have been very few. Results from isolated islet systems (22, 23) have shown that high glucose concentrations inhibit glucagon release. Pancreozymin was found

The results reported in this paper demonstrate, under the experimental conditions obtaining in this study, that high glucose concentrations suppress the secretion of pancreatic glucagon while low glucose concentrations enhance the secretion. The results thus support the concept of a role of glucagon as a "hormone of glucose need" as developed from various types of in vivo studies. The results show that acute changes in the glucose concentration of the perfusion medium exert an immediate effect on the secretion of pancreatic glucagon. It may be inferred that pancreatic glucagon may function in a moment to moment control of glucose concentration in blood, as has been suggested in the studies of Ohneda and coworkers (9).

No consistent inhibition of glucagon secretion was observed at the late high glucose concentration in most experiments, which might have been expected. However, glucagon release had been intensively stimulated with intestinal hormones or arginine, thus making suppression of glucagon less likely. It should be stressed in this connection, that the response pattern of glucagon and insulin after stimulation with the intestinal hor-
mones and arginine, and the dependence of the response pattern upon the glucose concentration present in the perfusing medium remained the same during the experiments, proving intact responsiveness of the alpha cells within the experimental period.

Gastrin, pancreozymin, as well as arginine were able to stimulate secretion of pancreatic glucagon, whereas secretin was without effect. Our results are thus consistent with in vivo data from experiments on triply catheterized dogs (5, 7, 8) with respect to the effects of pancreozymin, secretin, and arginine. Our finding, however, that gastrin, given as the synthetic human type I, stimulates glucagon release, has thus far not been reported. Recent data (19), that the synthetic C-terminal tetrapeptide amide of gastrin caused an elevation in the pancreaticoduodenal vein glucagon in dogs is interesting in this connection. However, it would be difficult to conclude from this finding that gastrin itself was effective in stimulating secretion of glucagon, as the C-terminal tetrapeptide amide is shared by both the gastrin and the pancreozymin molecule. The reason that Dupré, Curtis, Unger, Waddell, and Beck were unable to show a glucagon releasing effect of gastrin may be that a crude extract of hog antrum was used (2).

In addition, the present results demonstrate that the secretion of pancreatic glucagon after stimulation with gastrin, pancreozymin, and arginine follows a biphasic release pattern not previously described, similar to the characteristic response pattern described for insulin. The biphasic response pattern appears to be a characteristic feature of the secretion of the pancreatic hormones. A two pool model for insulin secretion has been proposed to explain this phenomenon (24, 25). In an earlier publication from our laboratory evidence for a feedback inhibition of insulin on insulin secretion has been reported in the isolated, perfused canine pancreas (13). The biphasic insulin response could be explained as a result of glucose or other stimulation plus feedback inhibition as has been originally discussed by Grodsky, Bennett, Smith, and Nemechek (20) and Bennett and Grodsky (21). The same hypothesis might also be relevant for the understanding of the biphasic glucagon response pattern, however, further experiments with special reference to this particular problem are necessary.

Although the high glucose concentration of 150 mg/100 ml in the perfusing fluid was unable to abolish the stimulatory effect of gastrin, pancreozymin, and arginine on the secretion of pancreatic glucagon, it did reduce the response in comparison with stimulation during perfusion with a low glucose concentration. From the point of view of the organism as a whole it is difficult to understand why glucagon secretion should be increased by gastrin, pancreozymin, or arginine at a glucose concentration of 150 mg/100 ml. Several explanations present themselves. Enhanced secretion in a situation where there is a demand for insulin might be explained by the ability of pancreatic glucagon to stimulate release of insulin (see later). On the other hand it would seem provident from the point of view of glucose homeostasis in a later phase if a glycogenolytic hormone-like glucagon was secreted simultaneously with insulin to prevent a possible postabsorptive hypoglycemia due to overwhelming aminogenic insulin secretion. Still a third possibility might exist, i.e. that glucagon apart from being an important hormone in carbohydrate metabolism is a hormone necessary for the
handling of amino acids (26, 27). This explanation is supported by the fact that a rise in glucagon is seen after stimuli associated with protein intake (28, 29). Finally, the concentrations of the intestinal hormones used in this study were rather high and maybe above a physiological range.

Pancreatic glucagon has been reported to be a potent stimulus of insulin secretion in vivo (30, 31) as well as in in vitro experiments (32–34). The precise nature of the stimulatory effect in vivo upon insulin secretion by pancreatic glucagon is not known. However, because of the rapid destruction of pancreatic glucagon and the negligible amount of pancreatic glucagon in peripheral blood, it may be assumed that if pancreatic glucagon is insulinogenic in vivo the stimulatory effect of pancreatic glucagon must take place locally immediately after secretion of the glucagon from the alpha cells of the islets of Langerhans and before recirculation. More direct evidence for such local eliciting effect of pancreatic glucagon might be offered, if the secretion of pancreatic glucagon, after stimuli such as gastrin, pancreozymin, and arginine, preceded secretion of insulin. Our results demonstrate that the secretion of the two hormones occurred simultaneously.

The present findings are consistent with the observations of Unger et al. made in dogs, but at variance with the results obtained in the isolated, perfused rat pancreas by Fussgänger et al. (35), who found that the secretion of glucagon after pancreozymin was delayed 5–10 min after the initial rise in insulin. However, the spontaneously increasing glucagon level during perfusion with a high glucose concentration, reported in this paper, may call for caution in the interpretation of the results.

The results of the time relationship experiments did not indicate an insulinogenic action of endogenous pancreatic glucagon. The finding in this study that secretin is able to stimulate secretion of insulin without any enhancement of pancreatic glucagon secretion speaks against a role of pancreatic glucagon as a necessary condition for insulin secretion after any kind of stimulus. Furthermore, the finding reported here that changes in insulin and glucagon secretion are consistently in opposite directions at high as compared with low glucose concentrations in the perfusing medium, also following stimulation with gastrin, pancreozymin, and arginine, speaks against such a role.

ACKNOWLEDGMENTS

I am very grateful to Professor Tyge Spånggaard, Department of Thoracic and Cardiovascular Surgery, and Professor Steen Olsen, University Institute of Pathology, Kommunehospitalet, Aarhus, Denmark for excellent laboratory facilities, and to Miss Mary Jo Jepsen and to Mrs. Karen Just for most conscientious and skillful technical assistance.
