ABSTRACT A single intratracheal instillation of pancreatic elastase in hamsters induces a lesion resembling human panacinar emphysema. This paper reports the occurrence of irreversible goblet cell metaplasia in the bronchial epithelium of hamsters similarly exposed to elastase. The goblet cell change was dose related; a dose of 0.1 mg/100 g body wt or less at 16 days, produced slight or moderate goblet cell metaplasia in fewer than half the animals, whereas 84% of animals treated with a dose between 0.2 and 0.5 mg/100 g body wt developed goblet cell metaplastic lesions, more than half of which were considered to be severe. The percentage of goblet cells in the epithelium of elastase-treated hamsters (32.5) was significantly higher (P < 0.005) than that of unexposed (12.2) and saline-exposed controls (18.7). All hamsters examined 6 and 12 mo after elastase treatment showed the lesion. The pathogenesis of the changes is unclear but the possibility is raised that the bronchial changes may be due to disturbance of an endogenous protease-antiprotease system. The findings suggest the hypothesis that, under appropriate circumstances, a single pulmonary insult in man could lead to a permanent lung injury demonstrating the anatomic lesions of both chronic bronchitis and panacinar emphysema.

INTRODUCTION

The increased frequency of severe panacinar emphysema in homozygous alpha-1-antitrypsin deficiency (ATD)1 is a well documented clinical entity (1–5). It has been suggested that the emphysematous process might result from the uninhibited action of elastase, or an elastase-like protease, liberated from polymorphonuclear leukocytes (PML) or alveolar macrophages (AM) within the lung (6–8). The intratracheal instillation of crystalline porcine, pancreatic elastase in hamsters induces a lesion with many of the anatomic and physiologic features of human panacinar emphysema. An increase in total lung volume and mean linear intercept (MLI) occur as early as 4 h after such injections (9), and later stages of the injury show destruction of alveolar walls as manifest by a significant decrease in internal surface area. These morphologic changes are accompanied by an increase in compliance, functional residual capacity, lung volume at −20 cm H2O transpulmonary pressure (analogous to human residual volume), and lung volume at 25 cm H2O transpulmonary pressure (analogous to total lung capacity) (10, 11). These abnormalities of structure and function have been proposed by Wright (12) as the criteria necessary for the development of an acceptable model of emphysema in experimental animals.

Further studies in our laboratories have demonstrated the simultaneous occurrence of irreversible bronchial goblet cell metaplasia in hamsters with elastase-induced emphysema and these observations form the basis for this report.

METHODS

Male golden hamsters (Mesocricetus auratus), weighing 100–140 g, were anesthetized with Brevital (methohexital sodium, Eli Lilly and Company, Indianapolis, Ind.), 5 mg/100 g body wt, and the trachea was intubated under direct vision. A single intratracheal injection of crystalline, porcine, pancreatic elastase (Whitman, EC 3.4.4.7, activity 26.8 U/gland hypertrophy; GCM, goblet cell metaplasia; H and E, hematoxylin and eosin; MLI, mean linear intercept; PAS, periodic acid-Schiff; PML, polymorphonuclear leukocytes.
mg) dissolved in physiological saline was administered in doses of 0.05, 0.1, 0.2, 0.25, 0.3, 0.4, or 0.5 mg/0.5 ml per 100 g body wt. Unexposed animals and those anesthetized and injected with a comparable volume of physiological saline served as controls. Animals were killed 16 days after the start of the experiment by exsanguination after an overdose of barbiturate given intraperitoneally. Lungs were fixed after excision by intratracheal instillation of 10% neutral buffered formalin at a hydrostatic pressure of 25 cm. Sagittal sections were taken from the parahilar area and 2–3 mm below the lateral pleurae. They were processed to paraffin embedding, sectioned at 5–10 μm, and stained with hematoxylin and eosin (H and E) and elastic-Van Gieson stains, and the periodic acid-Schiff (PAS) reaction.

In a second experiment, animals treated with one dose of 0.2 mg elastase/100 g body wt and untreated control animals were killed at 4 h, 1, 4, 8, 16, and 42 days, 3, 6, and 12 mo after injection and prepared for histological examination as described above.

In the first two experiments, the distribution and proportion of goblet cells in the intrapulmonary bronchial epithelium were assessed in paraffin sections by two independent observers with a five point scale in which 0 represented no, 1-slight, 2-moderate, 3-severe, and 4-very severe goblet cell increase. This assessment was made by comparison with standard slides. The score was termed the goblet cell index. Evaluation of interobserver agreement on the goblet cell index was determined by Spearman Rank Correlation Analysis (13). Goblet cells were identified in H and E sections as cells with pale, often foamy cytoplasm, and no cilia. In slides stained with PAS, goblet cells were easily identified by the purple-red reaction product due to their content of mucus. Determinations of MLI were made on paraffin slides from treated and control animals with the method described previously (10).

In a third experiment, hamsters were injected once with 0.2 mg of elastase/0.5 ml saline per 100 g body wt and killed 1, 4, 16, and 24 days later by intravascular fixation via a
needle inserted into the right ventricle while the animals were anesthetized. Locke’s solution at room temperature was perfused through the lungs for 5 min followed by 10 min of Karnovsky’s fixative (14) diluted 1:3 with 0.2 M cacodylate buffer, pH 7.4. The lungs were then removed and placed in containers of the same fixative overnight. The fixed lungs were sliced sagitally to reveal the major intrapulmonary bronchi. With a dissecting microscope, portions of the main stem bronchi and intrapulmonary airways with adjacent alveoli were cut transversely and removed as 1-mm cubes and postfixed in 2% osmium tetroxide in 0.2 M cacodylate buffer, pH 7.4, for 1 h at room temperature. The tissues were dehydrated through a graded ethanol series, embedded in Epon-Araldite, sectioned at 1–2 μm, and stained with methylene blue or basic fuchsin followed by alkaline methylene blue. Controls were untreated animals killed at 16 days and saline-treated animals (0.5 ml/100 g body wt) killed at 6 h, 2, 16, 33, and 180 days after exposure. Sections from the lungs of animals in this experiment were used to determine the percentage of goblet cells in the bronchial epithelium. Nonciliated cells which contained light- or dark-staining cytoplasmic droplets were scored as goblet cells. The number of goblet cells was expressed as a percentage of the total number of cells with a luminal border. All available sections with epithelium were used and a minimum of 600 total cells per animal was counted. The data in this experiment were analyzed by a double-tailed t test for nonpaired variables (15).

RESULTS

Goblet cell increase of varying severity was observed in the bronchi of the majority of elastase-treated hamsters and this increase will subsequently be referred to as goblet cell metaplasia (GCM). The lesion was most prominent in the large intrapulmonary bronchi but goblet cells were also seen in distal airways where they do not normally occur. The metaplastic epithelium was taller, individual goblet cells larger, and the PAS reaction of goblet cells more intense in elastase-damaged hamsters than in controls (Fig. 1). In treated animals, detachment of the

$ ^*$ The goblet cell index indicates the severity of GCM on a scale of no(0), slight(1), moderate(2), severe(3), or very severe(4) metaplasia.

1 Each value signifies the mean±SEM of MLI data averaged from the number of animals in parentheses.

§ One additional animal was assigned to this category but a poorly inflated lung precluded MLI determination.

$ ^*$ Doses in this range were 0.2, 0.25, 0.3, 0.4, and 0.5 mg/100 g body wt.
The parenchymal lesion as measured by MLI was as severe at 6 and 12 mo as it was at 3 mo, as originally described (10). Excellent interobserver agreement was obtained for the values of goblet cell index of treated and control animals as tested by the Spearman Rank Correlation ($r_p = 0.89$, $t = 11.9$, $P < 0.001$).

The quantitative assessment of GCM with plastic-embedded tissues is shown in Table II. The resolution of morphologic detail obtained with tissue embedded in plastic was much superior to that of tissue embedded in paraffin and goblet cells were easily identified by increased numbers of secretory droplets and absence of cilia (Fig. 4); as a result, lesions were observed for the first time at 1 day in plastic sections as compared with 8 days in paraffin sections. Saline-exposed animals had a significantly higher percentage of goblet cells (18.7%) than unexposed hamsters (12.2%) up to 16 days postinjection, but subsequently these values fell to normal levels. Elastase treatment resulted in a highly significant increase ($P < 0.005$) in goblet cells as compared with untreated and saline-exposed animals. The two animals sacrificed one day postelastase injection had a mean of 31.6% goblet cells and this abnormal proportion of goblet cells remained approximately the same in animals killed at 4, 16, and 24 days after exposure.

**FIGURE 3** Progression of GCM assessed in paraffin sections of lungs from hamsters either unexposed (open circles) or treated with 0.2 mg pancreatic elastase/100 g body wt. (closed circles). Mean values for goblet cell index and SEM are given.

The extent of GCM observed in paraffin sections at 16 days postinjection was related to the dosage of elastase (Fig. 2). Only 3 of 11 animals exposed to a dose of 0.1 mg/100 g body wt or less exhibited any GCM and the change was slight or moderate in severity. In contrast, 84% of the animals treated with 0.2–0.5 mg elastase/100 g body wt and killed at 16 days developed lesions, with 20% showing slight change, 16% moderate change, 43% severe, and 5% very severe GCM. Irrespective of the dose of elastase or time of killing, there appeared to be little correlation between the extent of GCM and severity of emphysema as assessed by values for MLI. Table I shows a summary of the data in support of this conclusion.2

The evolution of the lesion with time caused by a single dose of 0.2 mg elastase/100 g body wt is illustrated in Fig. 3. GCM was first observed in paraffin sections from two of four animals killed 8 days after elastase treatment. At 16 days, 8 of 10 animals had moderate or severe GCM and by 3 mo the percentage of hamsters demonstrating lesions had increased to 100%, a change which persisted to 12 mo.

* Significantly different (P < 0.01) from saline controls in Group I but not in Group II.
† Elastase-treated animals received one intratracheal injection of 0.2 mg of crystalline, porcine, pancreatic elastase/0.5 ml physiologic saline per 100 g body wt.
§ Significantly different (P < 0.005) from all control groups.

Hamsters seems an acceptable albeit imperfect model of human chronic bronchitis.

Previous attempts to clarify the pathogenesis of chronic bronchitis and emphysema with animal models have included exposure to nitrogen dioxide (22), sulfur dioxide (23–26), isoprenaline (27, 28), cigarette smoke (29–36), and enzymes (9, 10, 37–39). These agents cause lung damage with varying similarity to human disease. Persistent goblet cell increase has been produced in rats for at least 5 wk after 2 wk of repeated exposure to SO₂ (24) and in pigs for 2 mo after six daily injections of isoprenaline (28). Emphysematous lesions have not been reported in SO₂ or isoprenaline-treated animals. The present study shows that the hamster lung exposed to a single instillation of elastase develops not only a lesion with the morphological and some of the physiological characteristics of human panacinar emphysema (9–11), but also shows irreversible GCM. Relevant to this is the demonstration of GCM in the distal bronchioles of humans with chronic bronchitis and emphysema but not in those of subjects with bronchitis alone (40).

Why persisting GCM occurs after a single episode of...
elastase injury is obscure. It is an unusual pathological phenomenon because damaged epithelium tends to regenerate with restoration of the original architecture provided the general structure of the organ is preserved after injury. Thus, after denudation, gastric mucosa regenerates by passing through a stage of simple mucus-secreting tubular glands before the more complicated gastric structure is re-established (41). A similar repair pattern is followed in the damaged duodenum (42), while tracheal mucosa regenerates within 6 wk after curettage (43). Persistence of the mucus-secreting stage after elastase exposure suggests either that the hamster bronchus responds differently to injury than do other mucosal surfaces, or that there is a continuing injury. The nature of such a continuing injury is conjectural but it could result from the release of enzymes from increased numbers of PML or AM in the airways over an extended period. In support of this possibility is the finding that lung washout fluid has an elevated content of PML for up to 60 days after elastase exposure (44).

Endogenous proteases have been implicated as possible causal agents of emphysema in patients with ATD (6–8) and in cigarette smokers (45). This contention is supported by the production of emphysema-like damage in mice exposed to an enzyme extract from human AM (46) and in dogs exposed to homogenates from human and dog PML and to dog AM (47). Neither experimental study reported a bronchial lesion. It is of interest that antiproteases different from known serum inhibitors have been discovered in various lung components including the peripheral airspaces of dogs (48), the cytosol of human AM (49), and human bronchial mucus from patients with severe chronic bronchitis (50). The source of bronchial antiprotease is unknown but conceivably could be derived from goblet cells. If this is so, GCM in elastase-exposed hamsters and in humans with emphysema and chronic bronchitis could represent a mechanism for raising the level of elastase inhibitor in the lung.

The rapid increase in the percentage of goblet cells by 1 day in elastase-treated animals and to a lesser extent in saline-treated animals may be due to a surge in mucus synthesis by undifferentiated epithelial cells, i.e. potential goblet cells, in response to an irritant. It seems unlikely that cell division and differentiation could occur rapidly enough to account for this precipitous increase in goblet cells. Repair of the saline injury by 33 days is not surprising given the normal rate of turnover of respiratory epithelium but the cause of the persisting elastase injury remains to be determined.

Whether the elastase-induced bronchial lesion has an effect in altering airway dynamics is not known. We have observed GCM with papain-induced emphysema in hamsters3 and have shown that the emphysema-inducing property of papain is related to its elastolytic activity (51). Several investigators (52–55) have studied lung function in papain-induced emphysema and with one exception in the dog (53), found that alterations in airways dynamics were due to loss of elastic recoil rather than to increased peripheral airways resistance. However, all of these studies were carried out relatively early in the course of the lesion and, as we have shown here, GCM persists for at least 1 yr after the initial insult.

Our observation that a single dose of pancreatic elastase in hamsters causes permanent bronchial

---

damage as well as progressive emphysema may have profound implications for man. A chronic disease process may occur when a threshold for permanent damage is approached gradually by repeated, intermittent contact with low concentrations of an injurious agent. Alternatively, such a threshold may be reached abruptly upon exposure to a single overwhelming dose of an appropriate agent. The elastase-induced lesions in hamsters may be considered an example of the latter instance. A parallel human situation may be the reported permanent loss of exercise tolerance in 5 of 23 patients with chronic obstructive lung disease associated with ATD (1). The bronchial and parenchymal damage resulting from a single insult with elastase may persist and worsen due to a disturbed balance in a possible endogenous protease-antiprotease system. In view of the physiological and pathological similarities between elastase-induced lung damage in hamsters and human panacinar emphysema with chronic bronchitis, the present study suggests that a permanent anatomic lesion in both the bronchus and lung parenchyma in man could result from a single enzymatic injury from whatever source. The further implication is that a single acute lung injury may induce chronic, progressive pulmonary disease.
