Received for publication August 16, 2000, and accepted in revised form September 29, 2000.

Estrogen deficiency induces bone loss by upregulating osteoclastogenesis by mechanisms not completely defined. We found that ovariectomy-enhanced T-cell production of TNF-α, which, acting through the TNF-α receptor p55, augments macrophage colony-stimulating factor–induced (M-CSF–induced) and RANKL-induced osteoclastogenesis. Ovariectomy failed to induce bone loss, stimulate bone resorption, or increase M-CSF– and RANKL-dependent osteoclastogenesis in T-cell deficient mice, establishing T cells as essential mediators of the bone-wasting effects of estrogen deficiency in vivo. These findings demonstrate that the ability of estrogen to target T cells, suppressing their production of TNF-α, is a key mechanism by which estrogen prevents osteoclastic bone resorption and bone loss.

Introduction

Physiologic osteoclast renewal results from the differentiation of bone marrow monocytes (BMMs) into osteoclasts, a process induced by the simultaneous stimulation of osteoclast precursors by macrophage colony-stimulating factor (M-CSF) and a TNF-related factor known as receptor activator of NF-κB ligand (RANKL; also known as OPGL, TRANCE, or ODF) (1–3).

Although upregulation of osteoclast formation is recognized as the main mechanism by which estrogen deficiency induces bone loss (4, 5), the responsible cells and cytokines are not completely understood. Bone marrow stromal cells are essential for physiologic osteoclast renewal because they represent a major source of RANKL and M-CSF and provide a physical support for nascent osteoclasts (6). However, in stimulated conditions additional bone marrow cells contribute to regulate osteoclast formation by producing soluble and membrane-bound pro- and antosteoclastogenic cytokines. Among them are activated T cells, which stimulate osteoclast formation through increased production of RANKL, a phenomenon that contributes to inflammation-induced bone loss (7).

T cells express estrogen receptors, and estrogen directly regulates T-cell function and cytokine production (8–11). Moreover, T-cell subset alterations occur in women with postmenopausal osteoporosis (12, 13). Taken together, these findings suggest that T cells may contribute to enhanced osteoclast formation and induce bone loss not only during inflammation, but also in conditions of estrogen deficiency.

In this study we have investigated the role of T cells in ovariectomy-induced bone loss. We report that ovariectomy-enhanced T-cell production of TNF-α, which, acting through the TNF-α receptor p55, augments M-CSF– and RANKL-induced osteoclastogenesis. We also show that ovariectomy failed to induce bone loss, stimulate bone resorption, and increase osteoclast formation in T-cell deficient mice, establishing T cells as essential mediators of the bone-wasting effects of estrogen deficiency in vivo.

Methods

Experimental protocol. All animal procedures were approved by the Animal Care and Use Committee of Barnes-Jewish Hospital. Wild-type C57BL/6 mice, C57BL/6 homozygous (nu/nu) athymic nude mice (14), and heterozygous (nu/+ ) euthymic control littermates were obtained from Taconic Farms Inc. (Germantown, New York, USA). C57BL/6 mice lacking either TNF-α receptor 1 (p55– /–) or TNF-α receptor II (p75– /–) and wild-type controls of the same genetic background were obtained from Jackson Laboratories (Bar Harbor, Maine, USA). At 5 weeks of age mice were either sham operated or ovariectomized (OVX), and either left untreated or treated with 17β estradiol (0.16 μg/d) for 4 weeks as described (15, 16).

In vitro osteoclast generation, cytokine neutralization, and TNF-α assay. Bone marrow cells were either cultured unfractionated or depleted of stromal cells by adherence for 12 hours. The nonadherent fraction was used as a source of T cells and BMM precursors and was found to
be stromal cell free by using flow cytometry. T cells and BMMs were purified from bone marrow cells by positive immunoselection using MACS Microbeads (Miltenyi Biotec, Auburn, California, USA) coupled to anti-CD90 (Thy-1.2) for T cells or anti-CD11b (Mac-1α) Ab for BMMs. This procedure, which does not result in either T-cell or BMM activation (17), was found to generate greater than 95% pure preparations of CD90+ and CD11b+ cells, as assessed by flow cytometry.

Bone marrow cells (10⁶ cells per well) were cultured in 48-well plates with 1,25(OH)₂D₃ (10⁻⁸M) for 7 days to induce osteoclast formation. Nonadherent cells (10⁶ cells per well) were incubated for 7 days in 48-well plates with recombinant murine M-CSF (100 ng/ml) and soluble RANKL (100 ng/ml), which, at these concentrations, were found to induce maximal osteoclast formation. BMMs (10⁵ cells per well), T cells (10⁵ cells per well), and cocultures of purified BMM+ and T cells were incubated for 7 days in 96-well plates (200 µl of medium per well) with recombinant murine M-CSF (100 mg/ml) and soluble RANKL (100 mg/ml).

Culture media was collected after 3 days, and TNF-α was measured using ELISA (Quantikine; R&D Systems, Minneapolis, Minnesota, USA), as described (15). T-cell conditioned medium was prepared by culturing 10⁶ T cells/ml for 3 days. T-cell conditioned medium (100 µl) was added to a well containing 10⁵ BMMs and 100 µl of fresh medium (50% vol/vol). At days 3 and 5, 100 µl of the culture media was removed and replaced by 100 µl of conditioned media so as to maintain a total volume of 200 µl per well. TNFβP (5 µg/ml), IL-1ra (50 µg/ml; both kindly provided by Amgen Inc., Thousand Oaks, California, USA), and neutralizing anti–TNF-α, anti–IL-1, and anti–IFN-γ Ab’s (1 µg/ml; R&D Systems) were added at concentrations that are sufficient to neutralize (based on the manufacturer’s specifications) greater than 1,000-fold concentrations of TNF-α, IL-1, and IFN-γ to be present in monocyte and T-cell cocultures.

At the end of each experiment, cells were fixed and stained for tartrate-resistant acid phosphatase (TRAP). More than 98% of the TRAP-positive cells with more than three nuclei expressed pp60-Scr and cathepsin K, as assessed by immunohistochemistry, showed specific binding of labeled calciumin, and formed resorption pits in vitro (assessed as described) (15). Thus, the TRAP-positive multinucleated cells formed in these cultures were defined as osteoclasts.

T-cell apoptosis assay. Annexin-V flow cytometry was used to measure T-cell apoptosis, using the Apoptest kit (NeXins Research BV, Hoven, The Netherlands), according to the manufacturer’s instructions. Briefly, T cells from OVX and estrogen-replete mice were cultured in Aim V medium (GIBCO BRL, Gaithersburg, Maryland, USA) for 48 hours before labeling with the early apoptosis indicator Annexin-V-FITC (10 µl/106 cells) and the vital stain propidium iodide (10 µl of a 50 µg/ml stock). Cells were analyzed on a three-color Becton-Dickinson flow cytometer (FACScan; Franklin Lakes, New Jersey, USA). To facilitate FACScan calibration and interpretation of data, a positive apoptosis control was generated by labeling T cells in the presence of 0.1% paraformaldehyde, which permeabilizes the membrane, simulating apoptosis. A dead-cell control was generated by exposing T cells to 0.1% sodium azide for 20 minutes before labeling with propidium iodide and Annexin-V. Data represent average plus or minus SD of triplicate runs.

Bone marrow T-cell content assay. The percentage of T cells in the bone marrow of sham, OVX, and estrogen-replaced OVX mice was examined using flow cytometry. Bone marrow cells were isolated from the femurs of sham, OVX, and estrogen-replaced OVX mice (five per group) using centrifugation. Briefly, bones were inserted into a 0.6-ml microcentrifuge tube with a hole punctured in the bottom and placed into a 1.5-ml carrier microcentrifuge tube. Cells were extracted from the bones by centrifugation at 10,000 g for 1 minute. Recovered bone marrow cells were counted on a hemocytometer for each group before 10-minute incubation in 20% normal goat serum to block Fc receptors. Cells were labeled with (2 µg/10⁶ cells) CD3-FITC Ab (Sigma Chemical Co., St. Louis, Missouri, USA) in labeling buffer (PBS containing 1% BSA) for 40 minutes at 4°C. Cells were washed once with labeling buffer and analyzed using flow cytometry on a three-color Becton-Dickinson flow cytometer (FACScan). Positive fluorescence was assessed by comparing the result to cells incubated in an irrelevant isotype Ab. The percentage of gated T cells was multiplied by the total number of recovered cells from each group of mice to calculate the total number of T cells per group.

BMD and indices of bone remodeling. Trabecular bone mineral density (BMD) was measured in excised tibiae by peripheral quantitative computer tomography (pQCT) (XCT-960M; Nordland Medical Systems Inc., Fort Atkinson, Wisconsin, USA) as described (18), with modifications. Six cross-sections (two cortical at the mid-diaphysis and four trabecular at the proximal epiphysis) were scanned, and the data were analyzed using a threshold value of 200 mg/cm³ to select for bone and to exclude soft tissue. Cortical and trabecular bones were separated by “concentric peel” with the inner core (45%) defined as trabecular bone. An inner bone-density threshold of 400 mg/cm³ was selected to eliminate any residual or infiltrating cortical bone. Trabecular bone density (mg/cm³) was calculated using the internal software program CAL-CBD (Nordland Medical Systems Inc). The short-term in vitro reproducibility of this technique is 2%

Deoxypyridinoline (DPD) excretion was measured by ELISA using the Pyrilinks-D assay kit (Metra Biosystems Inc., Mountain View, California, USA) as described (15, 19). Serum osteocalcin levels were measured using the RIA kit of Biomedical Technologies Inc. (Stoughton, Massachusetts, USA).

Statistical analysis. Group mean values were compared by two-tailed Student’s t test or ANOVA and Fisher protected LSD test, as appropriate.
Bone marrow from sham, OVX, and estrogen-treated OVX mice was subjected to FACS using anti-CD90 Ab as described in Methods. Adherent cells were then recovered and analyzed by FACS and stimulated with 1,25(OH)2D3. At the end of the 4-week treatment period, bone marrow was harvested and stimulated with 1,25(OH)2D3. At the end of each experiment, cells were fixed and stained for TRAP. More than 98% of the TRAP-positive cells with more than three nuclei expressed pp60-src and cathepsin K, showed specific binding of labeled calcitonin, and formed resorption pits in vitro. Thus, the TRAP-positive multinucleated cells formed in these cultures were defined as osteoclasts.

While in nude mice bone marrow from OVX and estrogen-replete animals (both sham operated and estrogen-treated OVX mice) generated an equal number of osteoclasts in euthymic mice, bone marrow from OVX animals formed twice as many osteoclasts as that from estrogen-replete (E2-replete) mice (Figure 1a), thus suggesting that T cells mediate the stimulatory effect of estrogen deficiency on osteoclast formation in vitro.

Contributing to the enhanced osteoclastogenesis of estrogen deficiency are increased production of M-CSF (16, 20) and blunted release of the RANKL decoy receptor osteoprotegerin (OPG) (21) from bone marrow stromal cells. Since these cytokines are also produced by activated T cells (6), T lymphocytes from OVX mice may promote osteoclast formation through increased levels of M-CSF and free RANKL. However, analysis by RT-PCR revealed that T cells from OVX and estrogen-replete mice did not express detectable levels of M-CSF, RANKL, and OPG mRNAs (not shown), indicating that estrogen deficiency, unlike inflammation, does not induce the T-cell production of M-CSF and RANKL.

To determine if T cells from OVX mice increase osteoclast formation by enhancing the stromal-cell production of M-CSF and RANKL, nonadherent bone marrow cells (a stromal cell–depleted mixture of BMMs and lymphocytes) were stimulated with concentrations of RANKL and M-CSF, which maximally stimulate osteoclastogenesis. These experiments revealed that in euthymic mice osteoclast formation was still approximately twofold higher in cultures from OVX mice than in those from estrogen-replete mice. Confirming the regulatory function of T cells in nude mice ovariectomy did not increase M-CSF– and RANKL–induced osteoclast formation (Figure 1b). Thus, in conditions of estrogen deficiency T cells stimulate osteoclastogenesis through a mechanism unrelated to the presence of stromal cells and independent of regulation of OPG, RANKL, and M-CSF levels.

To further evaluate which cell population is the key target of estrogen in the bone marrow, BMMs (CD11b+...
cells) and T cells (CD90+ cells) were purified using immunomagnetic-positive selection from the bone marrow of OVX and estrogen-replete wild-type mice. BMMs were stimulated with saturating amounts of RANKL and M-CSF and cultured for 7 days in the presence of T cells purified from mice of different experimental groups. M-CSF and RANKL induced the osteoclastic differentiation of BMMs, and the magnitude of this phenomenon was similar for BMMs from OVX and estrogen-replete mice (Figure 2a). Importantly, the addition of T cells from OVX mice to BMMs harvested from all groups of donor mice increased M-CSF– and RANKL-induced osteoclast formation approximately 2.5-fold. In contrast, the addition of T cells from estrogen-replete mice to BMMs from all groups, had no effect on osteoclast formation.

M-CSF and RANKL stimulated BMMs seeded on dentine slices differentiated into osteoclasts capable of forming resorption pits. Consistent with the ability of T cells from OVX mice to augment osteoclast formation, resorption pits were approximately 2.8-fold more abundant in cocultures of BMMs and T cells from OVX mice, as compared with BMM cultured without T cells or cocultured with T cells from estrogen-replete mice (Table 1). Together, the data demonstrate that estrogen deficiency induces a T-cell activity capable of increasing the ability of M-CSF and RANKL to promote the formation of bone-resorbing osteoclasts.

T cell–produced TNF-α induces osteoclast formation through the p55 TNF receptor. Neutralization experiments revealed that the ability of T cells from OVX mice to potentiate M-CSF– and RANKL-induced osteoclast formation was completely prevented by the addition of either the TNF inhibitor, TNF-binding protein (TNFbp), or anti–TNF-α Ab (Figure 2a). In contrast, addition of either anti–TNF-β Ab, the IL-1 inhibitor IL-1-receptor antagonist (IL-1ra), or anti–IFN-γ Ab had no effect.

Experiments conducted by stimulating BMMs with cell-free T cell–conditioned medium demonstrated that T cells from OVX mice secrete a soluble activity (neutralized by anti–TNF-α Ab) that enhances RANKL- and M-CSF–induced osteoclast differentiation of BMMs from nonoperated control mice (Figure 3). T cells from OVX mice fail to increase RANKL- and M-CSF–induced osteoclast differentiation of monocytes lacking the p55 TNF-α receptor. Mean (± SEM) number of osteoclasts from three independent experiments (n = 6 wells per group). BMMs were purified from C57BL/6 mice lacking either TNF-α receptor 1 (p55–/–) or TNF-α receptor II (p75–/–) and WT controls of the same genetic background and cocultured with T cells derived from OVX or estrogen-replete WT mice in the presence of optimal concentrations of RANKL and M-CSF. *P < 0.05 compared with all groups.

Figure 2
T cells from OVX mice produce a soluble factor upregulating RANKL- and M-CSF–induced osteoclast formation, which is blocked by TNF-α neutralization. Mean (± SEM) of three independent experiments (n = 6 wells per group). *P < 0.05 compared with all other groups. (a) Cocultures of purified monocytes and purified T cells from OVX and estrogen-replete mice stimulated with optimal osteoclastogenic concentrations of M-CSF and RANKL. No osteoclast formation was observed in RANKL- and M-CSF–stimulated cultures of T cells in the absence of BMMs. Similarly, osteoclast differentiation of BMMs was not induced by stimulation with either RANKL or M-CSF alone, both in the presence or the absence of T cells (not shown). (b) Purified monocytes from intact mice stimulated with optimal osteoclastogenic concentrations of M-CSF and RANKL were cultured with either purified T cells from OVX and estrogen-replete mice or T cell–conditioned media (C.M.) from OVX and estrogen-replete mice. *P < 0.05 compared with all other groups.

Figure 3
T cells from OVX mice fail to increase RANKL- and M-CSF–induced osteoclast differentiation of monocytes lacking the p55 TNF-α receptor. Mean (± SEM) number of osteoclasts from three independent experiments (n = 6 wells per group). BMMs were purified from C57BL/6 mice lacking either TNF-α receptor 1 (p55–/–) or TNF-α receptor II (p75–/–) and WT controls of the same genetic background and cocultured with T cells derived from OVX or estrogen-replete WT mice in the presence of optimal concentrations of RANKL and M-CSF. *P < 0.05 compared with all groups.
These findings demonstrate that T cells from OVX mice upregulate osteoclast formation by production of soluble TNF-α.

To determine if BMMs are the target of T cell–produced TNF-α, T cells from OVX and estrogen-replete mice were cocultured with BMMs from both mice lacking either the p55 or the p75 TNF-α receptor (22) and wild-type (WT) mice of the same genetic background. We found (Figure 3) that T cells from OVX mice increased M-CSF– and RANKL-induced osteoclast formation when cocultured with BMMs from either WT mice or mice lacking the p75 receptor, while failing to do so in the presence of BMMs lacking the TNF-α receptor p55. The accumulated data demonstrate that T cells from OVX mice augment osteoclast formation through secretion of TNF-α and its binding to the BMM TNF-α receptor p55.

Ovariectomy increases T cell–produced TNF-α. Measurements by ELISA revealed (Figure 4a) the presence of approximately 200 pg/ml of TNF-α in the culture media of T cells from OVX mice, as compared with approximately 50 pg/ml in the media of T cells from estrogen-replete mice. BMMs from OVX and estrogen-replete mice produced similar amounts of TNF-α (~100 pg/ml). As a result, TNF-α levels were (Figure 4b) approximately twofold higher (~300 pg/ml) in the media from cocultures of T cells and BMMs from OVX mice than those from estrogen-replete mice (~150 pg/ml). Confirming that T cells and BMMs are the major sources of TNF-α in the bone marrow, the levels of this cytokine in cultures of unstimulated whole bone marrow were approximately 300 pg/ml in samples from OVX mice and approximately 150 in those from estrogen-replete mice (Figure 4a).

In previous studies we observed that ovariectomy increased the production of TNF-α by adherent mononuclear cells, a semipurified monocyte preparation. Since in the current study we found no effect of ovariectomy on the production of TNF-α by highly purified BMMs, we used FACS analysis to determine the T-cell content of adherent bone marrow cell preparations. We found (Table 2) that adherent bone marrow cells contain T cells (~10% of total cells) and that ovariectomy increases T-cell content approximately twofold. Taken together, the data suggest that the repressive effects of estrogen on adherent cell TNF-α secretion is due to decreased T-cell TNF-α production.

Dose-response studies revealed that recombinant TNF-α enhances M-CSF– and RANKL-induced osteoclast differentiation of CD11b+ cells in a dose-dependent manner, with a peak activity at approximately 1.2 ng/ml (Figure 4c). While 200 pg/ml of TNF-α was ineffective, 300 pg/ml of TNF-α (the amount present in cocultures of BMMs and T cells from OVX mice) induced approximately a twofold increase in M-CSF– and RANKL-induced osteoclast formation, thus demonstrating that the higher total level of TNF-α present in the culture media is responsible for the increase in osteoclast formation induced by T-cells from OVX mice. Levels of TNF-α up to 10 ng/ml did not induce osteoclast formation in the absence of RANKL.

Treatment of T cells from both OVX and estrogen-replete mice with 17β estradiol for 48 hours did not decrease the levels of TNF-α in the culture media (Table 3), suggesting that estrogen regulates T-cell TNF-α pro-
duction indirectly. To further investigate the mechanism by which T cells from OVX mice secrete increased amounts of TNF-α, unstimulated T cells were cocultured for 48 hours and their number counted at the end of the culture period. We found (Figure 5a) that the number of T cells was approximately threefold higher in cultures from OVX animals than in those from estrogen-replete mice. We also found that ovariectomy does not alter the number of cells undergoing apoptosis (Table 4), which suggests that ovariectomy increases T-cell proliferation. Attesting to the relevance in vivo of the regulatory effects of estrogen on T-cell proliferation, we found that bone marrow from OVX mice contained a larger number of T cells than that from estrogen-replete animals (Figure 5b). Together these data indicate that ovariectomy increases T cell–produced TNF-α by enhancing T-cell proliferation.

T cells were purified from the bone marrow of OVX and estrogen-replete mice and cultured for 2 days. The percentage of apoptotic cells was then determined as described in Methods.

Discussion

Estrogen prevents bone loss through multiple effects on bone marrow and bone cells, which result in decreased osteoclast formation (4, 5), increased osteoclast apoptosis (25), and decreased capacity of mature osteoclasts to resorb bone (26). Inhibition of osteoclast formation results primarily from the ability of estrogen to regulate the production of pro- and antiosseoclastogenic cytokines by bone and bone marrow cells (4, 5, 21, 27). Since T cells are now recognized as estrogen-regulated cells capable of producing essential estrogen-replete nude mice had similar urine DPD levels, a finding demonstrating that T cells mediate the effects of estrogen deficiency on bone resorption in vivo.

Since bone formation is coupled to resorption, the ovariectomy-induced increase in bone resorption is known to lead to an increase in bone formation. Accordingly, in euthymic controls, but not in nude mice, ovariectomy caused approximately a 50% increase in the serum levels of osteocalcin, a marker of bone formation (24) (Figure 6c), further demonstrating that T cells are pivotal for inducing the bone loss resulting from the effects of estrogen deficiency on bone remodeling.

**Figure 5**

Ovariectomy increases T-cell proliferation and bone marrow T-cell content. Mean (± SEM) of three independent experiments (n = 6 wells per group). A P < 0.05 compared with baseline. (a) Unstimulated T cells purified from OVX and estrogen-replete mice were cultured for 48 hours. At the end of the culture, T cells were counted. (b) Freshly isolated whole bone marrow was analyzed by FACS using anti-CD90 Ab. Total number of bone marrow cells was counted. Results are expressed as number of T cells per femur.
osteoclastogenic factors (7, 28), we have analyzed their contribution to the increased osteoclastogenesis and the bone loss induced by estrogen deficiency.

Bone densitometry and bone histomorphometry are established techniques for the detection of the bone loss induced by withdrawal of sex steroids. Analysis of bone mass by densitometry and histomorphometry correlates closely (29–33), although bone densitometry is not subjected to the sampling error that affects bone histomorphometry (34). Thus, in this study, bone density was measured in vivo by pQCT, a highly sensitive and precise technique that measures the density of the trabecular compartment of weight-bearing segments of the skeleton (18). The role of T cells in inducing osteoclastic bone resorption was assessed by measuring the urinary excretion of DPD, according to methods validated previously in the mouse (24). DPD excretion reflects both osteoclast number and osteoclast activity and correlates closely with histomorphometric indices of bone resorption (29).

We have found that ovariectomy failed to induce bone loss and stimulate bone resorption in T-cell deficient mice, thus demonstrating that T cells play a key role in mediating the bone-wasting effects of estrogen deficiency in vivo. Because T cell–deficient mice have normal bone morphology and only a modest increase in BMD, T cells are probably not required for normal bone remodeling. However, our results provide the first direct evidence that T cells cause the bone involution induced by estrogen deficiency.

Previous studies demonstrated neither the presence of a lower bone volume in nude mice (35) nor a failure of ovariectomy to induce bone loss in older athymic rats (36). However, in these earlier investigations bone volume was measured by bone histomorphometry, a less-sensitive technique than the densitometric method used in the current study (37). Moreover, mature athymic rats have a milder T-cell deficiency compared with young nude mice (14, 38) used in our investigation.

The data also demonstrate that T cells harvested from OVX mice produce TNF-α in an amount inadequate to induce osteoclast formation independent of RANKL, but sufficient to augment M-CSF– and RANKL–induced osteoclastogenesis through engagement of the TNF-α receptor p55. Additional studies in p55-deficient mice will be necessary to determine if the ability of TNF-α to stimulate bone resorption and induce bone loss in OVX mice is exclusively mediated by the p55 receptor.

Reports have shown that TNF-α at high concentrations (≥20 ng/ml) promotes osteoclast formation independently of RANKL, through NF-κB and Jun NH2-terminal kinase (JNK) activation (6, 39). Activation of these two signaling pathways is also responsible for the osteoclastogenic activity of RANKL (40, 41). Thus, it is likely that additive effects of RANKL and TNF-α on JNK and NF-κB activation accounted for the observed potentiating effect of TNF-α on RANKL– and M-CSF–induced osteoclastogenesis. Taken together, these observations provide a mechanism to explain how the small increase in T cell–produced TNF-α induced by estrogen deficiency leads to increased osteoclast formation and bone loss. However, since TNF-α stimulates the production of both M-CSF and RANKL (6, 42), our findings do not exclude the possibility that in conditions in which suboptimal levels of RANKL and M-CSF are present in the bone marrow, an additional mechanism by which T cell–produced TNF-α stimulates osteoclast formation is by increasing the production of these cytokines.

Another cytokine that has been implicated in the pathogenesis of ovariectomy-induced bone loss is IL-1 (43). Its level is increased in the bone marrow of OVX animals (15). Moreover, mice lacking the signaling IL-1 receptor IL-1R1 and animals treated with IL-1ra are protected against ovariectomy-induced bone loss (44, 45). IL-1 stimulates osteoclast activity through direct targeting of mature osteoclasts (6, 46), although it does not promote monocyte differentiation into osteoclasts (6). Thus, inhibition of TNF-α production accounts, at least in part, for the ability of E2 to block osteoclast formation, while the inhibitory effects of sex steroids on IL-1 production contributes to explain how E2 downregulates osteoclast activity.

**Figure 6**

Ovariectomy fails to induce bone loss and upregulate bone turnover in nude mice (n = 6 per group). *P < 0.05 compared with all other groups. 

*P < 0.05 compared with sham nu/nu. (a) Trabecular BMD (mean ± SEM) of the tibia was measured 4 weeks after surgery in excised tibiae using pQCT. (b) DPD excretion (mean ± SEM) at 4 weeks after surgery. (c) Serum osteocalcin levels (mean ± SEM) at 4 weeks after surgery.

The Journal of Clinical Investigation | November 2000 | Volume 106 | Number 10
A direct repressive effect of estrogen on IL-1 gene expression remains to be demonstrated. Moreover, studies have shown that TNF-α neutralization blocks IL-1 production, while IL-1 neutralization does not block TNF-α (47). Thus, it is likely that the increased bone marrow levels of IL-1 observed in OVX mice are, at least in part, a result of increased TNF-α production. When taken together, the available data indicate that while M-CSF and RANKL are essential for physiologic osteoclast renewal (6) and RANKL is responsible for the bone loss associated with inflammation (7), TNF-α plays a key causal role in the bone involution characteristic of estrogen deficiency.

Previous studies by us and others had revealed that ovariectomy increases the production of TNF-α by unfractionated bone marrow and adherent mononuclear cells, a partially purified preparation of peripheral blood monocytes (15, 48, 49). FACS analysis has now revealed that in estrogen-replete mice approximately 10% of adherent bone marrow cells are T cells and that ovariectomy increases their number approximately twofold. These findings are concordant with those of Abrahmsen et al. (50), who demonstrated that preparations of adherent mononuclear blood cells contain CD3+ CD56+ lymphocytes, a TNF-α–producing subset of MHC-unrestricted adherent T cells. In that study the number of CD3+ CD56+ T cells was decreased by estrogen treatment and inversely correlated to bone density. Thus, earlier findings in bone marrow and adherent cell cultures are consistent with the stimulatory effect of estrogen deficiency on the T-cell production of TNF-α observed herein.

Our data indicate that ovariectomy increases the proliferation of unstimulated T cells and the number of bone marrow T cells, which suggests that in vivo estrogen may regulate the number of TNF-α–producing T cells, rather than TNF gene expression. The finding that in vitro estrogen treatment of cultured T cells did not blunt the ability of T cells from OVX mice to produce TNF-α is consistent with this hypothesis and suggests that estrogen deficiency acts indirectly, perhaps targeting a population of bone marrow cells capable of activating T-cell proliferation.

The existence of such a regulatory mechanism has been described in models of T cell–mediated delayed-type hypersensitivity, where estrogen has been found to suppress T-cell proliferation through targeting of antigen-presenting cells (51, 52). Similarly, previous reports from our laboratory demonstrated that estrogen represses stromal cell–soluble M-CSF production through targeting of IL-1– and TNF-producing bone marrow cells, rather than through a direct effect on mature stromal cells (16, 27).

The results of this study, together with previous reports that mice treated with a TNF-α inhibitor (53) or insensitive to TNF-α due to the overexpression of a soluble TNF-α receptor (54) are completely protected against ovariectomy-induced bone loss, are relevant for the pathogenesis and the treatment of postmenopausal osteoporosis, because identification of the cellular and molecular targets of estrogen in bone may lead to the development of new therapeutic agents for postmenopausal osteoporosis.
