Chapel Hill, North Carolina 27514

Abstract Human growth hormone (hGH) is known to be a potent stimulator of somatomedin secretion in vivo. The induction of somatomedin by growth hormone has been difficult to study in vitro, however, because no organ containing a high concentration of somatomedin has been identified. Because fetal mouse explants have been shown to produce somatomedin in vitro, we have undertaken studies to determine whether postnatal human fibroblast monolayers also produce somatomedin, and if so, whether its production is regulated by other hormones. Quiescent human fibroblasts were exposed to serum-free minimum essential medium, and the medium was assayed for somatomedin concentration using a specific radioimmunoassay for somatomedin-C. A progressive rise in immunoreactive somatomedin to 0.08 U/ml per 10^6 cells per 24 h was observed over 72 h of incubation. This was an underestimation of the actual concentration of immunoreactive somatomedin since the amount measured following acid treatment was at least fourfold higher than in the untreated medium. Growth hormone stimulated immunoreactive somatomedin production in a dose-dependent manner: 5 ng hGH/ml = 0.1 U/ml per 10^6 cells; 50 ng hGH/ml = 0.25 U/ml per 10^6 cells. Platelet-derived growth factor and fibroblast growth factor were also stimulatory, but epidermal growth factor, thyroxine, or cortisol had no effect. Media that had been exposed to human fibroblasts stimulated DNA synthesis in BALB/c 3T3 fibroblasts (a cell type that does not produce somatomedin). Medium-derived immunoreactive somatomedin eluted from Sephacryl S-200 in two major peaks (150,000 and 8,000 mol wt). The higher molecular weight peak is similar to the one observed when whole serum was used. These studies provide a model system for studying the humoral and nonhumoral factors that control the biosynthesis of somatomedin by human tissues. Since immunoreactive somatomedin production may be a rate-limiting factor for fibroblast growth, the delineation of the hormonal control of somatomedin production should lead to a better understanding of the mechanisms controlling human fibroblast growth.

Introduction

The somatomedins, a family of growth hormone-dependent, insulinlike peptide growth factors, have been shown to be mitogenic for a variety of types of cultured cells (1-6). Cartilage from various species and fibroblasts derived from chick (7) and mouse (8) embryos fail to synthesize DNA or undergo mitosis normally when incubated in somatomedin-deficient serum. Evidence has been published, however, that hypopituitary serum is as effective as normal serum in increasing thymidine incorporation (7) and mitosis (9) by cultured human fibroblasts. Although such variables as species of cell origin (7), culture conditions (10), or differences in the methods by which the serum is prepared (11) might account partially for these differences in somatomedin dependancy, other explanations must be considered. For example, the effect of reducing the somatomedin concentration may be masked by a synergism between the small amounts of residual somatomedin remaining in hypopituitary serum and peptides that are not growth-hormone dependent, such as platelet-derived growth factor (PDGF) (12). Alternatively, it is possible that the effect of somatomedin deficiency in serum is masked by the

somatomedin production of the cultured cells themselves. Indeed, there are reports of production and release of growth factors into medium of cultured transformed cells (13–15) and cells that proliferate in very low serum concentrations (16). Explants of fetal mouse and rat liver (17, 18) and a number of other fetal mouse tissues are able to secrete immunoreactive somatomedin into the culture medium. Atkinson et al. (19) have reported recently that monolayer cultures of human embryonic lung fibroblasts likewise release immunoreactive somatomedin. Because immunoreactive somatomedin production might be a rate-limiting step for human fibroblast replication, we have assessed the capacity of cultured postnatal human fibroblasts to produce immunoreactive somatomedin. We have also observed the effects of human growth hormone and other mitogens contained in serum on immunoreactive somatomedin production.

METHODS

Human fibroblasts were purchased from the Human Mutant Genetic Cell Repository, Camden, N. J. Dermal fibroblasts (strain 498) from a normal 3-year-old donor were used in these studies. BALB/c 3T3 fibroblasts were a gift of Dr. Charles Stiles. Dulbecco's modified minimum essential medium (DME) was purchased from Flow Laboratories, Inc., Rockville, Md. Eagle's minimum essential medium (MEM), fetal calf serum, penicillin, and streptomycin were purchased from Gibco, Grand Island Biological Co., Grand Island, N. Y. All cultures were plated in plastic petri dishes (Falcon Labware, Div. Becton, Dickinson & Co., Oxnard, Calif.). Bovine serum albumin (Sigma Chemical Co., St. Louis, Mo., fraction V) was determined to be free of immunoreactive somatomedin-C when assayed at a concentration of 50 mg/ml. [methyl-3H]Thymidine (6 Ci/mM) was purchased from New England Nuclear, Boston, Mass. Porcine insulin (PI 5682) was a gift from Eli Lilly Company, Indianapolis, Ind. Immunochemical grade human growth hormone (hGH) (HS 1144) and bovine growth hormone (B-16) were obtained from the National Pituitary Agency, Baltimore, Md. The human hormone preparation was 0.97 U hGH/mg, <1% contamination by other proteins, and is free of fibroblast growth-factor-like biological activity (8). The somatomedin-C used in these studies was purified to homogeneity as determined by multiple criteria (20). Mouse epidermal growth factor and bovine fibroblast growth factor were purchased from Collaborative Research Inc., Waltham, Mass., and the manufacturer stated that they were >99% pure. PDGF was prepared by the following method: outdated human platelets were washed in 17 mM Tris HCl, pH 7.5, and concentrated by centrifugation. The platelet pellet was freeze-thawed, then boiled for 10 min. The boiled extract was centrifuged at 3,000 g for 30 min to remove particulate debris. The supernatant fluid was further purified using CM Sephadex chromatography, Pharmacia Fine Chemicals, Piscataway, N. J. (21). PDGF prepared in this manner is purified 250-fold over crude platelet homogenate and contains no somatomedin-C by radioimmunoassay. Human platelet poor plasma (PPP) was prepared by placing freshly drawn blood in prechilled plastic centrifuge tubes without anticoagulant and immediately centrifuging at 5,000 g. After removing the supernatant fluid and repeating the centrifugation at 10,000 g for 30 min, the supernate was heated to 56°C for 30 min and centrifuged at 5,000 g for 20 min. The resulting supernatant fluid was dialyzed against 0.15 M sodium chloride and stored at −20°C until used. PPP prepared by this method is free of PDGF-like biological activity (12). Hypopituitary PPP was obtained from two hypopituitary donors who were markedly deficient in immunoreactive somatomedin-C (<4 ng/ml), and was prepared in the same way as normal PPP.

Cell culture techniques. Cells were cultured in 10-cm dishes (Falcon 3001) in MEM containing 10% fetal calf serum (FCS) and were maintained in a humidified incubator containing 5% CO2. The medium was changed every 3rd d and the cells were harvested by trypsinization and replated once weekly (split ratio, 1:4). Both stock and test cultures were tested for mycoplasma contamination (22) and were found uncontaminated. To assess immunoreactive somatomedin production, fibroblasts (between the 8th and 12th passage) were plated in 1.5-cm wells (Falcon 3008) at a density of 5,000 cells/cm2 in MEM containing 10% FCS, penicillin (100 U/ml), and streptomycin (100 μg/ml). This medium was changed every 3 d until the cells reached confluency. 3 d after the last medium change, confluent monolayers were washed three times with serum-free MEM and incubated with 0.5 ml serum-free MEM containing 0.1% bovine serum albumin (BSA). The media were sampled at the times indicated in the Results section, either by removing of an aliquot and replacing it with an equal volume of MEM-0.1% BSA, or by removing the entire 0.5 ml incubation volume. Samples were immediately centrifuged at 1,400 g for 10 min to remove particulate debris and the supernatant fluids were stored at −20°C until they were assayed for somatomedin content. Growth hormone and other mitogens were tested at various concentrations by adding the hormone (in MEM-0.1% BSA) to fibroblast monolayers that had been washed free of serum-containing medium. Samples were then processed and collected in the manner described above. At each time point, duplicate monolayers were washed twice, the cells were removed by trypsinization, and a 0.5-ml aliquot was placed in 9.5 ml of 0.15 M NaCl. Each sample was counted three times in a particle data counter (Coulter Electronics, Inc., Hialeah, Fla.) and the mean of six determinations was used as the cell number per monolayer.

Quantitation of immunoreactive somatomedin in culture media. The preparation of somatomedin-C used for iodination had a specific activity of 10,142 U/mg protein.3 It was iodinated with sodium 125I (Amersham-Searle, Chicago, Ill.) by a chloramine T method (23). Specific activities varied from 190–350 μCi/μg. The iodinated hormone was purified by affinity chromatography using the IgG fraction of a rabbit anti-human somatomedin-C antibody coupled to Sephrose 4B (Pharmacia). The radioimmunoassay used rabbit anti-human somatomedin-C antibody in a final dilution of 1:12,000 (24). This assay is highly specific for somatomedin-C and insulin-like growth factor I, which produce identical curves of competition (25). Insulin-like growth factor II, somatomedin-A, or multiplication-stimulating activity III-2 have potencies of 2.4, 5, and 1.2%, respectively. The immunoassay reference standard is an aliquot of the somatomedin preparation used for iodination that has been judged by multiple criteria to have a purity not <90% (20).

In addition to measurement of immunoreactive soma-
fibroblast in unextracted fibroblast culture media, media were assayed after treatment with acid. In the acid treatment, 1.0 ml of the medium sample was incubated with 1.0 ml of 2 N acetic acid at 37°C for 30 min. The pH of the incubation mixture was 3.6. The acidified sample was then lyophilized to dryness and reconstituted in 0.03 M phosphate buffer, pH 7.5. The immunoreactive somatomedin content of both native and acid-treated media is expressed as U/ml per 10⁶ cells.

Medium samples that had been acidified and neutralized were tested for their ability to compete with 125I-somatostatin for binding to placental membranes. Medium aliquots of 5–200 μl, 125I-somatostatin (20,000 cpm/tube), and 200 μg placental membrane protein were incubated in Tris 0.05 M, pH 7.4, for 16 h. After this incubation the membranes were washed, and the bound radioactivity was determined. The standard for this assay was a partially purified preparation of somatomedin-C which had been calibrated in the radioimmunoassay (RIA) against pure somatomedin-C.

Measurement of bioactive somatomedin in culture media. BALB/c 3T3 fibroblasts, which do not produce immunoreactive somatomedin, were plated at d-1,000 cells/cellotest well in DME containing 10% FCS, penicillin (100 U/ml), and streptomycin (100 μg/ml). Confluent monolayers were washed twice with serum-free DME and exposed for 5 h to DME containing partially purified PDGF (500 ng/well). This medium was removed and replaced with DME containing 5% hypotaurine PPP and either pure somatomedin-C (1–7 ng/ml) or conditioned MEM (10–60% of final volume). After 48 h incubation, DNA synthesis was measured by a previously described autoradiographic method (26).

Characterization of immunoreactive somatomedin in media. 20 ml of medium that had been exposed to fibroblast monolayers for 48 h were dialyzed (Spectropor 3, mol wt cut off 3,500) against 1 liter of 0.025 M phosphate buffer, pH 7.4, for 48 h with four changes of buffer. The retained material was lyophilized to dryness, reconstituted with 1.0 ml water, applied to a 1.6 x 80-cm Sephadryl S-200 column, and eluted with 0.05 M phosphate buffer, pH 7.4. Each fraction was acidified for 30 min (pH adjusted to 3.6), lyophilized to dryness, reconstituted in 0.03 M phosphate buffer (pH 7.4), and assayed for immunoreactive somatomedin content. An additional 10-ml aliquot of medium was acidified with an equal volume of 2.0 M acetic acid, final pH 3.6, and lyophilized to dryness. The material was reconstituted in 0.5 ml acetic acid containing 10,000 cpm 125I-somatostatin-C, applied to a 1.6 x 80-cm Sephadex G-50 column and eluted with acetic acid. The fractions were lyophilized to dryness and reconstituted in 0.03 M PO₄ buffer, pH 7.4, before assay.

RESULTS

Measurement of immunoreactive somatomedin in fibroblast medium. Although confluent monolayer cultures of human fibroblasts were demonstrated to produce a peptide that reacted in our RIA, the amount of this material in medium was generally underestimated. When 20–120 μl of medium that had been exposed to cells for 72 h were incubated with 125I-somatostatin-C in immunoassay buffer, the curve of competition obtained was not parallel to that obtained using pure standard (Fig. 1). Because the somatomedins have been shown to circulate in plasma bound to binding proteins, and cultured cells have been demonstrated to produce substances with somatomedin binding activity, we were concerned that this lack of parallelism was the result of binding proteins in the fibroblast culture media. We also observed that when graded quantities of pure somatomedin-C were added to the medium, the recovery of the added peptide was incomplete (~23%). This incomplete recovery was not the result of degradation of somatomedin-C during immunoassay, because incubation of 125I-somatostatin-C with medium for 48 h (4°C or 24°C) resulted in no loss of binding when samples were subsequently exposed to an excess of somatomedin antibody. Several perturbations of medium were tested to eliminate the effect of these interfering substances, and to achieve parallelism and full recovery. Heating media at 24°C, 37°C, or 56°C for variable periods of time had no effect. Reducing the pH of medium samples to 3.6 for 30 min and subsequent neutralization, however, produced dose-response curves parallel to the pure standard (Fig. 2). 62% of pure somatomedin-C that had been added to acidified media samples was recovered, and there was an eightfold enhancement of somatomedin activity over media which had not been acid treated. In subsequent studies, therefore, media were subjected routinely to acid treatment before assay.

Production of immunoreactive somatomedin by fibroblasts. Confluent cultures of human fibroblasts were washed three times with serum-free MEM and exposed to MEM containing 0.1% BSA. No

D. R. Clemmons, L. E. Underwood, and J. J. Van Wyk
immunoreactive somatomedin could be detected in the third wash. Medium samples removed at 24, 48, and 72 h showed a progressive rise in immunoreactive somatomedin concentration (Fig. 3). The quantity of immunoreactive somatomedin present in the media at 72 h was two times greater than the concentration present in the MEM-10% FCS in which the cells originally had been grown and 12 times greater than the immunoreactive somatomedin content of the cellular cytosol at the start of the incubation.4

Several additional experiments were performed to exclude the possibility that immunoreactive somatomedin in FCS had been taken up by the cells and then released. When 125I-somatomedin-C (4 ng/ml of medium) was incubated with fibroblast cultures for 48 h and the cells were washed 3 times, only 1.3% of the labeled hormone remained in the cell-associated fraction. In another experiment, the MEM-0.1% BSA

---

4 The somatomedin concentration in the cytosol was determined as follows: the cells from 12 monolayers were removed by scraping into prechilled 0.05 M phosphate buffer, pH 7.4, homogenized and centrifuged at 100,000g for 60 min. The supernatant fraction was assayed for somatomedin-C concentration. Controls for recovery included exposure before homogenization of 125I-somatomedin-C (20,000 cpm) and pure unlabeled somatomedin-C (1 ng/ml). Recovery was >98% by both methods.

Confluent fibroblast monolayers were washed with serum-free MEM, then exposed to MEM-0.1% BSA (control) or MEM-0.1% BSA plus hGH, 10 ng/ml. Additional wells contained either of these media plus cyclohexamide (50 μM). At the times indicated, media from quadruplicate plates were removed and stored for somatomedin determination.

**FIGURE 2** Dose-response curve for acid-treated medium. Medium (1.0 ml) that had been exposed to human fibroblasts for 24 h was acidified by adding 1.0 ml of 2.0 M acetic acid (final pH 3.6). After 30 min at 37°C, the mixture was neutralized using 0.015 ml of 0.1 N NaOH. The dose-response curve obtained using acidified medium (●) is compared to that obtained using pure somatomedin-C (○).

**FIGURE 3** Production of somatomedin-C by human fibroblast cultures. Confluent human fibroblast cultures were exposed to serum-free MEM containing 0.1% BSA. Media were removed at the times indicated, and the somatomedin concentration determined by RIA.
Growth hormone stimulation of immunoreactive somatomedin production. When graded amounts of hGH were incubated for 24 h with confluent fibroblast monolayers containing only MEM-0.1% BSA, there was a dose-dependent (1–40 ng hGH/ml) increase in somatomedin production (Fig. 4). These fibroblasts, therefore, are sensitive to hGH and display increases in immunoreactive somatomedin production at concentrations of growth hormone within the range normally found in human serum.

Other stimuli of immunoreactive somatomedin production by fibroblasts. In an additional series of experiments, confluent human fibroblasts were exposed to MEM-0.1% BSA containing either hGH (10 ng/ml), PDGF (500 ng/ml), or PDGF plus growth hormone. With these stimuli, cultured fibroblast media exhibited a progressive increase in immunoreactive somatomedin production over time (Fig. 5). The combination of PDGF and growth hormone was additive at the concentrations tested. A variety of other factors had little effect on immunoreactive somatomedin production (Table II). In addition to PDGF and hGH, stimulatory effects were noted when fibroblast growth factor was added, but not by cortisol, thyroxin, mouse epidermal growth factor, or porcine insulin. Bovine growth hormone, added over a concentration range 5–500 ng/ml, showed significant stimulation only at the 500 ng/ml concentration. This result indicates that bovine growth hormone is ∼1% as potent as hGH in inducing the formation of immunoreactive somatomedin in this system.

Biological and physicochemical properties of immunoreactive somatomedin produced by fibroblasts. To determine whether fibroblast-derived somatomedin can stimulate cell division, conditioned medium was added to BALB/c 3T3 cell monolayers in the presence of 5% hypopituitary PPP (<4 ng/ml immunoreactive somatomedin-C). For comparison, additional monolayer cultures received graded amounts of unlabeled somatomedin-C plus 5% hypopituitary PPP. The addition of 120 μl conditioned MEM resulted in stimulation of DNA synthesis that was equal to that produced when hypopituitary PPP plus 7 ng/ml somatomedin-C was added (Table III). A dose response to conditioned medium was demonstrable over the concentration range tested (10–60% vol/vol).

Conditioned medium that had been acidified and neutralized (see Methods) was tested for its capacity to compete with 125I-somatomedin-C for binding to placental membrane receptors. A parallel dose-response curve was obtained and the somatomedin concentration by the receptor assay was estimated to be 12 vs. 9.2 ng/ml by RIA.

On Sepharic S-200 chromatography, the immunoreactive material in the media migrated in three distinct peaks (Fig. 6). Approximately 60% of the activity eluted in the 140,000 mol wt region and ∼30% migrated in a region similar to free somatomedin.

![Figure 4](image-url) Effect of hGH on somatomedin-C production by fibroblasts. Confluent human fibroblast cultures were exposed to increasing concentrations of hGH in MEM-0.1% BSA for 24 h. The results are expressed as units of somatomedin-C per milliliter per 10⁶ cells.

![Figure 5](image-url) Effect of hGH and PDGF on SM-C production. Confluent monolayers were exposed to serum-free MEM containing no addition (○), 10 ng/ml (△) hGH, 500 ng/ml PDGF (●), or hGH plus PDGF (□) in 0.1% BSA. After incubation for 24 h, the media were harvested and somatomedin-C content was determined. Results are expressed as units of somatomedin-C per milliliter per 10⁶ cells.

Microtest wells containing confluent quiescent BALB/c 3T3 cells (10,000 cells/well) were exposed to PDGF (1.0 μg/well) in DME for 5 h. These media were then removed, the monolayers were washed twice, and serum-free MEM that had been exposed to human fibroblast cultures for 48 h was added (in the percentage of the total volume listed) along with DME containing 5% hypothymus PPP (total vol = 0.2 ml). The somatomedin content of the conditioned medium was 0.12 U/ml. This concentration of pure somatomedin-C has been shown by us and others (39) to stimulate fibroblast replication. After 48 h of incubation, each well was washed twice with 70% methanol and DNA synthesis was measured by autoradiography. 200 nuclei were counted in each well and each result (the mean of two wells) is expressed as the percentage of cells labeled. Additional wells received a known quantity of pure somatomedin-C standard instead of serum-free medium and the results were determined as described.

A minor peak was detectable in the 90–100,000 mol wt region. Medium that was acidified and neutralized, then preincubated for 16 h at 4°C with 125I-somatotelin-C (20,000 cpm), and chromatographed on Sephacryl S-200 showed no activity in the 140,000 mol wt region. Approximately 60% of the activity now eluted in the 70 and 35,000 mol wt regions and 40% in the mol wt region corresponding to free somatomedin. The 125I-somatotelin-C also migrated in the region corresponding to free somatomedin. Similar chromatographic results were obtained when medium was acidified and chromatographed on G-50 Sephadex at pH 3.6. Under these conditions, ~71% of the immunoreactive material appeared in the void volume, and 29% chromatographed at K_d = 0.5, the region corresponding to free somatomedin (Fig. 7).

DISCUSSION

Observations of Burk (27), Shodell (15), and Stoker et al. (28) suggested that certain types of cultured cells have the capacity to secrete growth factors into serum-
free medium. Dulak and Temin (29) extended these observations when they isolated and characterized multiplication-stimulating activity from medium which had been exposed to fibroblast cultures for 24 h was acidified (pH 3.6) and incubated for 18 h at 4°C with $^{125}$I-somatostatin-C (SM-C). This mixture was applied to a Sephadex G-50 column (20 x 1.6 cm) and eluted with acetic acid, pH 3.6. O, OD$_{280}$; E, somatostatin (units per milliliter x 10$^{-3}$); O, $^{125}$I-SM-C (cpm).

Figure 7 Gel filtration chromatography of medium on Sephadex G-50. Medium which had been exposed to fibroblast cultures for 24 h was acidified (pH 3.6) and incubated for 18 h at 4°C with $^{125}$I-somatostatin-C (SM-C). This mixture was applied to a Sephadex G-50 column (20 x 1.6 cm) and eluted with acetic acid, pH 3.6. O, OD$_{280}$; E, somatostatin (units per milliliter x 10$^{-3}$); O, $^{125}$I-SM-C (cpm).

free medium. Dulak and Temin (29) extended these observations when they isolated and characterized multiplication-stimulating activity from medium which had been exposed to buffalo rat liver cells. More recent studies by Rechler et al. (18) have identified multiple peptides with mitogenic activity in this conditioned medium. The physicochemical and growth-promoting properties of these peptides are similar to purified somatostatin-C and to multiplication-stimulating activity which had been isolated from calf serum. More recently, Todaro and Delarco (30) have shown that SV-40 transformed cells produce a polypeptide which crossreacts in the multiplication-stimulating activity–radio-receptor assay. Other important growth factors such as colony-stimulating factor (31), macrophage growth factor (32), and nerve growth factor (33) are produced by a variety of cultured cells. Cultured human fibroblasts have also been reported to produce a small peptide which stimulates endothelial cell division (34) and a macromolecule which enhances fibroblast attachment and stimulates replication in the presence of serum (35). The chemical characteristics of these substances and their spectra of biologic activity have not been defined.

It has generally been assumed that growth factors such as somatostatin must be transported through blood to their target tissues to stimulate growth. The demonstration by others that growth factors are produced by cultured cells prompted us to question whether human fibroblasts might produce immunoreactive somatostatin that in turn might stimulate proliferation within the culture. Our results, as well as those of Wiedman et al. (36), indicate that fibroblasts are capable of producing a factor(s) that crossreacts in immunoassays for basic somatostatin. In humans it is not known if this property is limited to fibroblasts; however, studies using fetal mouse tissue explants suggest that it may be a phenomenon common to more than one cell type. Based on the observations that cartilage is not sensitive to direct stimulation by growth hormone (37), it can be assumed that this tissue and perhaps others require blood-borne somatostatin for growth.

Preliminary studies indicate that a large portion of the immunoreactivity in cultured fibroblast medium is in an acid-stable, high molecular weight form. Similarities between this material and somatostatin-C purified from human plasma are suggested by the findings that the former (a) reacts with specific somatostatin-C antiserum, (b) crossreacts with somatostatin-C in the placental membrane radio-receptor assay, and (c) stimulates DNA synthesis in BALB/c 3T3 cells, which require the addition of somatostatin-C for replication.

Precise measurement of the immunoreactive somatostatin-like material is difficult, probably because of interference by the somatostatin binding proteins contained in the culture medium. Acidifying and then neutralizing media corrected the nonparallelism of media immunoreactivity, eliminated protein-binding
activity, and significantly enhanced immunoreactivity. Similar findings have been observed with media taken from cultured explants of fetal mouse tissues (17); however, the loss of 125I-somatomedin-C is contrary to results reported using human serum (38). Since acid treatment does not result in conversion to a lower molecular weight form, its enhanced apparent immunoreactivity may result from better access of antibody to previously inaccessible somatomedin. Alternatively, some of the apparent immunoreactivity in the macromolecular fraction after acid treatment could result from interference of binding proteins in the RIA. This, however, appears unlikely because we observed parallelism between pure somatomedin-C and the acid-treated media and there is no 125I-somatomedin-C binding on gel chromatography.

The major question concerning growth hormone's mechanism of action has been whether it stimulates cell replication directly, or acts through the induction of an intermediary substance such as somatomedin. Our results seem to strengthen the possibility of an indirect action. They demonstrate that the growth hormone, at concentrations comparable to those in human serum, stimulates cultured postnatal human fibroblasts to produce immunoreactive somatomedin. We have presented evidence recently that supports the hypothesis that somatomedin mediates the growth-promoting effects of growth hormone on cultured cells (39). Specifically, we have observed that when medium containing hypopituitary PPP and growth hormone is removed and replenished every 2 h, replication of fibroblast cultures does not proceed at a normal rate. Frequent changing of medium containing hypopituitary PPP and purified somatomedin-C, however, allows replication to proceed normally. These observations suggest that somatomedin production is necessary for normal fibroblast replication and the effect of growth hormone on fibroblasts is mediated through somatomedin production.

The potential importance of growth hormone-regulated immunoreactive somatomedin production by fibroblasts is that it might be the mechanism whereby growth hormone stimulates generalized cell growth. In contrast, stimulation of fibroblast immunoreactive somatomedin production by PDGF represents a non-growth hormone-dependent mechanism by which fibroblast replication in culture could be stimulated. PDGF has been proposed as a growth factor which stimulates the rapid proliferation of fibroblasts during wound healing (40). Stimulation of immunoreactive somatomedin production by PDGF could be one mechanism by which these events occur.

The system we have used for assessing immunoreactive somatomedin production has a number of uses. In addition to serving as a tool for the study of the hormonal control of immunoreactive somatomedin biosynthesis, it could be useful in assessing non-hormonal factors that regulate immunoreactive somatomedin production, and as an alternate means for determining the biological potency of growth hormone preparations.

There is evidence that fibroblast growth factor stimulates cellular proliferation by a mechanism similar to PDGF (8). The capacity of a highly purified fibroblast growth factor preparation to substitute in our system for partially purified PDGF suggests that a single peptide in the platelet factor preparation may be responsible for stimulation of immunoreactive somatomedin production. The failure of epidermal growth factor, thyroxin, and insulin to stimulate immunoreactive somatomedin production suggests that the process is specific for certain peptides and implies that epidermal growth factor and insulin stimulate mitosis through mechanisms independent of immunoreactive somatomedin production. Our studies indicate that bovine growth hormone is a weak stimulator of immunoreactive somatomedin production. The concentrations of bovine growth hormone required are comparable to those necessary to compete with hGH for binding to receptors in human tissue (41).

The observation that hypopituitary serum is as potent as normal serum in stimulating fibroblast replication suggests that immunoreactive somatomedin production by the fibroblast cultures may be nullifying any differences in the intrinsic mitogenic capacity of these two types of sera. The findings of Moses et al. (7), that hypopituitary serum stimulates DNA synthesis by cultured cells, could be explained if their hypopituitary test serum contained enough PDGF to stimulate in vitro production of immunoreactive somatomedin that, in turn, stimulated proliferation of their cultured fibroblasts. Alternatively, other somatomedins that are slightly growth hormone-dependent and, therefore present in hypopituitary serum, may stimulate replication in this cell type.

Although immunoreactive somatomedin generally has been considered to be a blood-borne hormone with widespread stimulatory effects on cell proliferation, our findings indicate that fibroblast-derived somatomedin may regulate proliferation of selected cell types at or near its site of production. Such local regulation could provide a mechanism whereby focal cellular proliferation could be coordinated without stimulation of adjacent tissues. Such a mechanism might be an important component of normal physiologic processes such as wound healing, or in disorders of cellular proliferation such as atherosclerosis.

ACKNOWLEDGMENTS

We gratefully acknowledge Dr. W. J. Pledger's gift of partially purified platelet-derived growth factor and his advice in planning cell culture studies. We wish to thank Ms. Diane
Chapin and Eyunonne Bruton for their technical assistance and Ms. Cindy Sullivan for her help in preparing this manuscript.
