Abstract

We studied the effect of the same genetic but different environmental factors on total immunoglobulin and specific antibody levels in twins reared apart. Sera were analyzed from 26 monozygotic (MZ) and 10 dizygotic (DZ) twin pairs, who were separated on average 2 mo after birth and reared apart. Total IgM, IgG, and IgA were measured by single radial diffusion. Specific antibodies of each isotype to tetanus toxoid, to polyvalent and type 14 pneumococcal capsular polysaccharides were measured by a solid-phase antigen-enzyme-labeled antigen immunoassay. One-way analysis of variance showed intrapair total Ig and antibody levels to be more highly correlated in MZ compared with DZ twins. Our results indicate that genetic factors are more important than environment in regulating these humoral immune responses.

Introduction

Total Ig and specific antibody (Ab) levels are influenced by both genetic and environmental factors. In rodents, the magnitude of the antibody response to defined antigens is controlled by immune response genes in the major histocompatibility complex (1, 2). Rats reared in a germ-free environment with minimal antigenic exposure have very low total Ig levels, which only increase after exposure to normal environmental antigens (3). In humans, the relative contribution of genetic compared with environmental factors is unknown. Limited information is available on how these factors interact in determining the quality and quantity of the humoral immune response. Studies of conventional twins, who share similar environments, have shown that total Ig levels correlate more closely in monozygotic (MZ) than dizygotic (DZ) twins, indicating a genetic influence (4–6). Our investigation was done to determine the effect of the same genetic but dissimilar environmental backgrounds on Ig- and isotype-specific antibody levels through utilization of twins separated soon after birth and reared apart. Our results indicate that genes are more important than environment in determining these humoral immune responses.

Methods

Twins reared apart. Sera from 26 pairs of MZ twins reared apart were evaluated (7). Included in this group were one MZ pair from a set of triplets (MZ sisters and a brother), and three pairs from a set of MZ male triplets. There were 12 female and 14 male MZ pairs, ranging in age from 11 to 58 yr. Sera were collected in Minneapolis from both members of each pair simultaneously, stored within 48 h at −70°C, shipped to Denver on dry ice, and again stored at −70°C. Two MZ female twins were concordant for adult onset diabetes mellitus and two MZ male twin pairs were concordant for childhood onset asthma. One MZ female pair was concordant for Hashimoto’s thyroiditis and one was discordant for thyroid cancer. Sera from 10 pairs of DZ twins reared apart, including 2 pairs from the triplet set of MZ sisters and a brother, were similarly collected and stored. In the DZ group, there were five female and three male pairs, plus the two female-male pairs from the triplet set. Their ages ranged from 30 to 55 yr. One DZ male pair was concordant for adult onset asthma and two pairs of DZ female twins were discordant, one for rheumatoid arthritis, and one for multiple sclerosis.

The average age at time of separation was 2 mo with a range from birth to 4 yr. One pair was black. The others were all Caucasian. Zygosity diagnosis was based on analyses of eight blood type systems, four serum proteins, six erythrocyte enzymes, fingerprint ridgectount, ponderal index, and cephalic index (8).

Ig quantitation. Concentrations of IgG, IgA, and IgM were determined by single radial immunodiffusion using commercial plates (Immunoplates; Calbiochem-Behring Corp., La Jolla, CA). The experimental variation on repeated determinations of these sera ranged was under 15%.

Isotype-specific antibody quantitation. An enzyme immunosorbent assay (EIA) was developed to determine isotype-specific (IgG, IgA, and IgM) antibody to tetanus toxoid and pneumococcal (Pn) capsular polysaccharides. Fluid tetanus toxoid, 200 μl of a 1:50 dilution of Purogen (Wyeth Laboratories, Philadelphia, PA) in phosphate-buffered saline (PBS; 0.01 M phosphate, pH 7.2), was adsorbed to 96-well microtiter plates (Linbro, Flow Laboratories, McLean, VA). Adsorption of Pn polysaccharide was done by first activating polyvalent Pn (Pneumovax; Merck, Sharp and Dome, Rahway, NJ) and type 14 Pn (Lederle Laboratories, Pearl River, NY) polysaccharide with cyanuric chloride, next crosslinking the Pn to poly L-lysine (Sigma Chemical Co., St. Louis, MO), and then coating onto microtiter plates following the method of Gray (9). The coating concentration for the individual polysaccharides was 1 μg/ml in PBS.

Sera were diluted 10³ in PBS containing 0.05% Brij detergent, and 200-μl aliquots were incubated in the antigen-coated wells for 16–18 h at room temperature. The wells were washed extensively, and then horseradish peroxidase-labeled monospecific goat IgG antibody to human IgG, IgA, or IgM (Tago, Burlingame, CA) were added at concentrations of 500 ng/ml for 1 h at 23°C. After washing, substrate was added for 1 h and the reaction stopped by addition of 50 μl 4 N sulfuric acid, and the OD at 492 nm was determined in an automatic spectrophotometer (Flow Laboratories).
Paired twin sera were run in duplicate in adjacent wells for each assay without knowledge of zygosity. Total Ig were quantitated in milligrams per milliliter and isotype-specific antibody titers in relative OD units by relating all determinations to a standard serum obtained from a 26-yr-old white male physician who had been immunized with polyvalent Pn vaccine (Pneumovax) 4 wk previously and with tetanus toxoid in childhood. The standard serum was included on all antibody assays and assigned a titer of 100 OD units. This standard serum contained 84 μg/ml of IgG anti-tetanus toxoid antibody as determined with a solid-phase radioimmunoassay by Dr. A. Saxon (UCLA Medical School, Los Angeles, CA) and 190.7 μg/ml total (IgG, IgA, and IgM) antibody to 12 capsular polysaccharides present in the polyvalent Pn vaccine (Pneumovax) and 10.7 μg/ml total antibody to type 14 polysaccharide as determined by the Farr ammonium sulfate assay.

Specific activity. The specific activity for antibody of each isotype was obtained by dividing the relative OD titer by the concentration of IgG in milligrams per 10 milliliters and IgA and IgM in milligrams per milliliter. These concentrations were arbitrarily used to yield specific activities which approximated the OD titer values.

The experimental variation in the EIA antibody determinations was <10% for the 3 isotypes and 3 antigens in repeat assays on different days on 13 sets of twin sera run in duplicate. Variability of the EIA was determined by dividing the replicate (between times) variance by the total (between individual) variance. Variation in duplicate results on the same serum at the same time was <5%.

Statistical analysis. Total Ig and isotype-specific antibody titer

Figure 1. Comparison of IgG in twins reared apart. DZ (○) results are in the upper left and MZ (●) in the lower right of each scatter diagram. The higher value in each DZ pair is plotted on the ordinate and in each MZ pair on the abscissa. (A) Total Ig. DZ: r = 0.40; F, 0.43; P, NS. MZ: r = 0.82; F, 9.9; P < 0.001. (B) IgG anti-tetanus toxoid. DZ: r = 0.27 (0.17); F, 1.75 (1.44); P, NS (NS). MZ: r = 0.72 (0.63); F, 6.09 (4.37); P < 0.001 (<0.001). (C) IgG anti-polyvalent

Pn. DZ: r, 0.37 (0.06); F, 2.17 (1.13); P, NS (NS). MZ: r, 0.52 (0.61); F, 3.20 (4.10); P < 0.01 (<0.001). (D) IgG anti-type 14 Pn. DZ: r, 0.17 (0.08); F, 1.40 (1.18); P, NS (NS). MZ: r, 0.62 (0.55); F, 4.11 (3.48); P < 0.001 (<0.01). r, intratwin pair correlation coefficient; F, F-ratio; P, significance. The specific activity results are shown in parenthesis.
were evaluated by one-way analysis of variance of the paired twin and triplet sera counting the MZ triplets (individuals a, b, and c) as three pairs, i.e., a-b, b-c, and a-c, and the MZ-DZ triplets as one MZ pair (a-c) and two DZ pairs (a-b and b-c). The results in the 26 MZ pairs are depicted in the lower right half and the DZ pairs in the upper left half of the scatter diagrams which follow. One-way analysis of variance yields the "intraclass correlation" which, for identical twins reared apart, is a direct estimate of heritability, provided that environments are uncorrelated (10). The intraclass correlation coefficients for the 21 quantifiable variables (3 total Igs, 9 antibody titers with the 3 isotypes and 3 antigens; and 9 specific antibody activity titers) were obtained by dividing the mean square variance between (MSB) minus the mean square variance within (MSW) twin pairs by the MSB plus MSW variances and the F-ratio by dividing the MSB variance by the MSW variance. Calculations were done on a programmable desk calculator (Compucorp model 145E; Computer Design Corp., Los Angeles; CA) and significance values obtained from F-ratio and correlation coefficient tables.

**Results**

**Total serum Ig concentrations.** The distribution of Ig concentrations in the MZ and DZ pairs are shown in Figs. 1 A, 2 A, and 3 A. In the MZ twins reared apart, the within pair correlation coefficients were highly significant for all three isotypes: IgG (r = 0.82, P < 0.001), IgA (r = 0.80, P < 0.001), and IgM (r = 0.82, P < 0.001). By contrast, in the DZ twins reared apart, the total concentrations of individual Igs were

---

**Figure 2.** Comparison of IgA in twins reared apart. See Fig. 1 for explanation of symbols. (A) Total IgA. DZ: r, 0.34; F, 2.07; P, NS. MZ: r, 0.80; F, 9.13; P < 0.001. (B) IgA anti-tetanus toxoid. DZ: r, 0.17 (0.24); F, 1.42 (1.63); P, NS (NS). MZ: r, 0.25 (0.53); F, 1.68 (3.26); P, NS (<0.05). (C) IgA anti-polyvalent Pn. DZ: r, 0.66 (0.24); F, 4.85 (1.63); P < 0.025 (NS). MZ: r, 0.16 (0.27); F, 1.39 (1.76); P, NS (NS). (D) IgA anti-type 14 Pn. DZ: r, 0.68 (0.57); F, 5.28 (3.66); P < 0.01 (<0.05). MZ: r, 0.57 (0.73); F, 3.63 (6.48); P < 0.001 (<0.01).
not significantly correlated: IgG \( (r = -0.40) \), IgA \( (r = 0.34) \), and IgM \( (r = 0.35) \).²

Isotypic antibody titers. Anti-tetanus toxoid titers (Figs. 1 B, 2 B, and 3 B) were highly correlated in the MZ twins for IgG \( (r = 0.72, P < 0.001) \) and IgM \( (r = 0.59, P < 0.001) \), but not for IgA \( (r = 0.25) \). In the DZ twin pairs, IgM titers \( (r = 0.54, P < 0.05) \) were significantly correlated but not IgG \( (r = 0.27) \) or IgA \( (r = 0.17) \). Anti-polyvalent Pn titers (Figs. 1 C, 2 C, and 3 C) in the MZ twin sera pairs were significantly correlated for IgG \( (r = 0.52, P < 0.01) \) and IgM \( (r = 0.59, P < 0.001) \), but not for IgA \( (r = 0.16) \), while the intrapair correlations in the DZ twins was significant for IgA \( (r = 0.66, P < 0.025) \) but not for IgG \( (r = 0.37) \) nor IgM \( (r = -0.18) \).

² A summary of each twin's Ig and isotype antibody titers and specific activity results, along with demographic data, are available from Dr. Kohler on request.

Figs. 1 D, 2 D, and 3 D show that anti-type 14 Pn antibody in the MZ twins was significantly correlated for all three isotypes: IgG \( (r = 0.60, P < 0.001) \), IgA \( (r = 0.57, P < 0.001) \), and IgM \( (r = 0.60, P < 0.001) \). In the DZ twins, a significant correlation was found for IgA \( (r = 0.68, P < 0.01) \) and IgM \( (r = 0.58, P < 0.05) \) anti-type 14 Pn but not for IgG \( (r = 0.17) \).

Specific activity of antibody. When the isotypic antibody levels were expressed in terms of specific activity rather than total antibody, the within pair F-ratio and correlation increased in the DZ group for IgG anti-poly Pn \( (0.52 \text{ to } 0.61) \) but not for anti-type 14 Pn or tetanus toxoid, and for all IgA antibodies (anti-poly Pn \( [0.16 \text{ to } 0.27] \), anti-type 14 \( [0.57 \text{ to } 0.73] \), and anti-tetanus toxoid \( [0.25 \text{ to } 0.53] \)). No increases in \( F \) and \( r \) occurred when IgM antibody was calculated in terms of specific activity. In the DZ group, the intrapair specific activity correlations were increased for IgA anti-tetanus \( (0.17 \text{ to } 0.24) \)
and for IgM anti-poly Pn (−0.18 to 0.58) antibodies. The specific activity results are shown in parenthesis in Figs. 1–3.

Essentially no change in results occurred when one MZ twin was randomly eliminated from each set of triplets to yield one MZ pair from the MZ triplets and one MZ and one DZ pair from the unlike sex triplets (MZ sisters and brother).

Discussion

Our results indicate that genetic factors are more important than environmental exposures in determining total Ig and specific antibody levels in man. Overall, the within twin pair concentrations of total IgG, IgA, and IgM and isotype antibody titers were significantly correlated in the MZ but not the DZ twins, despite growing up in different environments. The average age at separation was 2 mo and by history each individual twin had been immunized with tetanus toxoid but not pneumococcal polysaccharide vaccine. Presumably, by age 11, all subjects had variable but sufficient natural exposure to multiple different Pn serotypes; however, despite this exposure, polyvalent and type 14 antibody titers were more significantly correlated in the MZ than in the DZ twins. The fact that significant correlations occurred in four of nine antibody titers in DZ twins compared with seven of nine in MZ twins indicates a genetic influence in the former group also (Table 1). The presence of rheumatoid arthritis and multiple sclerosis in single members of two DZ female twin pairs could not explain the differences observed in DZ within pair total Ig concentrations and isotypic antibody levels.

Previous investigations have been limited to total Ig levels in twins reared together and most have demonstrated a significant MZ within pair correlation of IgG, IgA, and IgM in addition to IgD and IgE concentrations when compared with DZ twin sera (4–6, 11, 12). Since the same environment was shared by these twins, it can be assumed that, overall, cumulative antigenic exposure was also similar. A primary genetic influence on total Ig concentrations was suggested by the more closely correlated levels in the MZ twins. Specific antibody levels were not measured in these studies and any potential within pair environmental effects were not discernible.

There are few studies concerning genetic influence on specific antibody levels in humans. One recent study reported higher total antibody responses to group B meningococcal polysaccharide vaccination in persons with the KM (1) kappa light chain allotype, a gene product of human chromosome 2 (13). A second study reported significantly higher IgG anti-gliadin antibody in patients with gluten-sensitive enteropathy who were G2M(N)-positive than in G2M(N)-negative patients, despite the fact that both groups were on a gluten-free diet (14). G2M(N) is an IgG heavy chain allotype coded for by a gene on chromosome 14. There was no association of anti-gliadin antibody with the chromosome 6 coded major histocompatibility class I and II antigens, B8 and DR3. IgE antibody to ragweed and grass pollens are also influenced by genetic factors (15, 16).

In spite of different environmental exposures to antigens, the predominant factor(s) determining total Ig and isotypic antibody levels in these twins was genetic rather than environmental. We postulate that sufficient cumulative natural exposure to Pn capsular polysaccharides had occurred to initiate antibody synthesis and that genetic factors were responsible for the significant correlations in anti-Pn antibody levels in the MZ twins. If so, in very young MZ twins with different cumulative environmental exposures, antibody titers would be less highly correlated. When antibody titers were compared in the MZ twins under age 25 to those over age 50, there were no differences in the correlations. However, IgG anti-tetanus titers but not anti-poly Pn or anti-type 14 IgG titers were found to be inversely correlated with age presumably because puncture wounds treated with booster toxoid immunizations occur less frequently with advancing age. The occasional large differences in intra MZ twin pair isotypic antibody titers are best explained by marked variation in toxoid immunizations and natural exposure to Streptococcus pneumoniae which outweighed genetic influences. Since the MZ within pair correlations were higher for total Ig concentrations (0.65 to 0.82) than for IgM and IgG antibody titers (0.52 to 0.72), and were usually lower for within pair antibody specific activity, this genetic regulation may influence total Ig concentrations more than concentrations of isotypic antibody. We predict that antibody responses to immunization with defined antigens would show an even greater correlation of within pair responses in MZ twins. It is important to note, however, that the general health of each twin, as well as zygosity, will also be an important regulatory influence since total Ig and isotypic antibody levels differ greatly in MZ twins who are discordant for systemic lupus erythematosus or the acquired immune deficiency syndrome (P. F. Kohler, unpublished observations).

Acknowledgments

Our sincere thanks to Ms. Patt Anderson for technical help, Ms. Kathy Utschinski for graphics and manuscript preparation, and Dr. Gary Zerbe for advice on statistical analysis. The type 14 Pn polysaccharide was generously provided by Lederle Research Laboratories, Pearl River, NY. We thank Dr. Andrew Saxon and Dr. Gerald Shiffman for quantitative analysis of antibody in the standard serum. Dr. Janet Stewart’s and Dr. Henry Claman’s critical review of the manuscript is appreciated.
