Molecular and Biochemical Basis of Intermediate Maple Syrup Urine Disease
Occurrence of Homozygous G245R and F364C Mutations at the E1α Locus of Hispanic-Mexican Patients

Abstract

Maple syrup urine disease (MSUD) is caused by a deficiency of the mitochondrial branched-chain α-keto acid dehydrogenase (BCKAD) complex. The multienzyme complex comprises five enzyme components, including the E1 dehydrogenase with a heterotetrameric (αβ3) structure. Four unrelated Hispanic-Mexican MSUD patients with the intermediate clinical phenotype were diagnosed 7 to 22 mo after birth during evaluation for developmental delay. Three of the four patients were found homozygous for G to A transition at position 895 (exon 7) of the E1α locus, which changes Gly-245 to Arg (G245R) in that subunit. The remaining patient was homozygous for T to G transversion at base 1,253 in the E1α gene, which converts Phe-364 to Cys (F364C) in the gene product. Transfection studies in Elα-deficient lymphoblasts indicate that both G245R and F364C mutant Elα subunits are unable to significantly reconstitute BCKAD activity. Western blotting showed that both mutant Elα subunits in transfected cells failed to efficiently rescue the normal Elβ through assembly. The putative assembly defect was confirmed by pulse-chase labeling of El subunits in a chaperone-augmented bacterial overexpression system. The kinetics of initial assembly of the G245R Elα subunit with the normal Elβ was shown to be slower than the normal Elα. No detectable assembly of the F364C Elα subunit with normal Elβ was observed during the 2 h chase. Small amounts of recombinant mutant El proteins were produced after 15 h induction with isopropyl thiogalactoside and exhibited very low or no El activity. Our study establishes that G245R and F364C mutations in the Elα subunit disrupt both the El heterotetrameric assembly and function of the BCKAD complex. Moreover, the results suggest that the G245R mutant Elα allele may be important in the Hispanic-Mexican population. (J. Clin. Invest. 1995. 95:954–963.) Key words: branched-chain α-keto acid dehydrogenase complex • El dysfunction • pulse-chase labeling • defective heterotetrameric assembly • molecular chaperones

Introduction

Maple syrup urine disease (MSUD)1 or branched-chain α-keto-nuria is an autosomal recessively inherited deficiency in the mitochondrial branched-chain α-keto acid dehydrogenase (BCKAD) complex. The biochemical basis of this disease is the inability to metabolize branched-chain α-keto acids (BCKAs) derived from the essential branched-chained amino acids (BCAAs) leucine, isoleucine, and valine. The elevated BCAAs and BCKAs may have severe clinical consequences including ketoacidosis, mental retardation, and neurological impairment. Variations in clinical presentations have led to the classification of MSUD into five clinical phenotypes, i.e., classic, intermediate, intermittent, thiamine-responsive, and E3-deficient (1, 2). The classic form, which comprises 75% of MSUD patients, is manifested within the first 2 wk of life with poor feeding, lethargy, seizures, coma, and death if untreated. Intermediate MSUD is associated with elevated BCAAs and BCKAs, with progressive mental retardation and developmental delay without a history of catastrophic illness. The diagnosis is usually delayed for many months. An intermittent form of MSUD may have normal levels of BCAAs, normal intelligence and development until a stress, e.g., infection, precipitates decompensation with ketoacidosis and neurologic symptoms, which are usually reversed with dietary treatment. Thiamine-responsive MSUD is similar to the intermediate phenotype but responds to pharmacologic doses of thiamine with normalization of BCAAs. The E3-deficient MSUD is caused by defects in the dehydrogenase (E3) component of the BCKAD complex that is common to the pyruvate and α-ketoglutarate dehydrogenase complexes. Patients with E3 deficiency have dysfunction of all three enzyme complexes, and patients usually die in infancy with severe lactic acidosis (3).

The mammalian BCKAD complex is a mitochondrial multi-enzyme complex, which catalyzes the oxidative decarboxylation of the three BCKAs derived from BCAAs (4, 5). The enzyme complex is organized around a cubic core comprising 24 identical dihydrolipoyl transacyslase (E2) subunits. The other enzyme components attached to the E2 core include a branched-chain α-keto acid decarboxylase (E1), a dihydrolipoamide dehydrogenase (E3), a specific kinase and a specific phosphatase. The latter two enzyme components are responsible for the regulation of BCKAD complex by phosphorylation (inactivation)/de-

---

1. Abbreviations used in this paper: BCAA, branched-chain amino acid; BCKA, branched-chain α-keto acid; BCKAD, branched-chain α-keto acid dehydrogenase; E1, branched-chain α-keto acid decarboxylase; E2, dihydrolipoyl transacylsylase; E3, dihydrolipoyl dehydrogenase; Hsp, heat-shock protein; IPTG, isopropyl thiogalactoside; MSUD, maple syrup urine disease; SSCP, single-stranded conformational polymorphism; TEV, tobacco etch virus; TPP, thiamine pyrophosphate.
phosphorylation (activation) (6). The E1 component is a heterotetramer consisting of two E1α (47,000 Mr) and two E1β (37,000 Mr) subunits. The E3 component, a flavoprotein, is a homodimer. Both kinase and phosphatase are products of single genes. Multiple copies of the six distinct subunits of the BCKAD complex are synthesized in the cytosol and imported into the mitochondria (7). In the matrix space of this organelle, mature subunits are assembled into a multienzyme complex of 4–5 × 10^6 daltons.

MSUD is genetically heterogeneous, and mutations in E1α, E1β, E2 and E3 loci have been identified (1). Some of these mutations have been characterized at the molecular and biochemical level. For example, the Y593N substitution in E1α, which is present in Mennonite patients with classic MSUD, was shown to impede E1 assembly resulting in the preferential degradation of E1β (8, 9). However, these studies were confined to classic MSUD patients, and little is known about the variant forms of MSUD. In the present report, we describe the clinical and molecular characterization of four MSUD patients with an intermediate phenotype. These patients, all of Hispanic-Mexican origin, were identified many months after birth during evaluation for developmental delay, without acute neurologic symptoms. Molecular studies show that three of the four unrelated patients are homozygous for a missense mutation in the E1α locus. The remaining patient is homozygous for a second mutation also in the E1α gene. Both mutations produce inactive or slightly active BCKAD complex when the mutant peptide was transiently expressed in E1α-deficient lymphoblasts. Moreover, by pulse-chase labeling of E1 subunits synthesized in Escherichia coli, we show that these mutations in E1α alter the kinetics of assembly with E1β.

Methods

Case reports. A.G., a male Mexican infant, appeared normal during the first few months of life except for mild feeding problems. Although development seemed normal during the first 5–6 mo of age, he was unable to sit without support until 11 mo of age. During infancy, he sustained several 30-s tonic seizures associated with fever. He presented at 12 mo of age for evaluation of his developmental delay and possible seizure disorder. Physical exam was significant for relative microcephaly (10th percentile compared with length and weight, 75th and 25th percentiles, respectively), mild hypotonia with cerebellar ataxia. MSUD was diagnosed on the basis of elevated serum BCAAs and alloisooleucine (Table 1). After initiation of BCAA-restricted diet, neurologic evaluation showed normal tone, reflexes, and cerebellar function.

J.B. was a 5-lb male born to Mexican parents of small stature (<10th percentile). During infancy, he had formula intolerance and exhibited significant developmental delay, manifested by inability to sit, stand, or crawl by 17 mo old. He had two brief tonic/clonic seizures at 4 mo, which were easily controlled with phenobarbital. At 17 mo, examination was significant for developmental delay; head circumference, length, and weight at the third percentile; and generalized hypotonia. Analysis of serum amino acids demonstrated elevated BCAAs and alloisooleucine, suggesting MSUD. Improved development occurred during dietary treatment, but hyperkinesis and psychomotor delay persisted.

P.R., a Mexican female, demonstrated excessive irritability, poorly tolerated her formula, and showed developmental delay with poor head control, inability to roll over and poor social interactions during the first 4–5 mo of life. Qualitative analysis of serum amino acids showed elevated amino acids including BCAAs. She was placed on 1 g protein/kg per day diet with improvement in her reactions to auditory and visual stimuli, decreased ataxia and a weight gain. At 7 mo, physical examination revealed length 75th, weight 50th, and head circumference 75th percentiles with generalized hypotonia and developmental delay. Quantitative serum amino acids revealed elevated BCAAs and alloisooleucine. Strict dietary treatment resulted in further improvement in her development (Table 1).

B.S. was a 6 lb 8 oz female born to a 14 yr-old-Mexican primigravida. Although irritable as an infant she had a good appetite and tolerated standard formula. During her first year of life she was hospitalized four times with pneumonia. At 9 mo, developmental delay was noted and an EEG was normal. Between 12 and 22 mo, three uncontrolled tonic/clonic seizures occurred and were controlled with phenobarbital. At 20 mo, she was readmitted to the hospital with an infection and evaluated for her developmental abnormalities, being unable to stand or control head movements. Physical examination showed length 30th, weight 60th, and head circumference 50th percentiles with diffuse hypotonia, brisk reflexes, and poor motor control. Psychomotor functioning was at a 3–4 mo level. An EEG showed a disorganized pattern with paroxysmal spikes, and a CT scan revealed increased white matter lucency consistent with deficient myelinization. A diagnosis of MSUD was made by metabolic studies (elevated serum BCAAs and alloisooleucine), however, compliance with therapy was poor, and her most advanced milestones were independent walking with a broad-based gait, and a few words (<10) were learned. During periods of appropriate BCAA restriction, her motor and developmental skills demonstrated marked improvement.

Cell cultures and other cell lines. Fibroblast cultures were derived from skin biopsies and grown in monolayer culture as previously described (10). Intermediate MSUD patients A.G., J.B., P.R., and B.S. and classic MSUD patient P.V. were provided by Drs. Arthur Beaudet and Edward McCabe (Baylor College of Medicine, Houston, TX). GM-649 was purchased from the Human Genetic Mutant Cell Repository (Camden, NJ). B.F. was a classic MSUD patient of African-American descent provided by Dr. David Valle (John F. Kennedy Institute, Baltimore). K.U. is a classic Caucasian MSUD patient provided by Dr. Selma Snyderman (New York University Medical Center, New York).

L.C. is a classic MSUD patient obtained from the Cell Repository at McGill Medical Center (Montreal, Canada). H.H. is a classic Mennonite MSUD patient provided by Dr. Marc Yudkoff (Childrens Hospital of

* Total dietary leucine tolerated to maintain plasma leucine concentrations of 200–400 μM (normal range 50–130 μM). †Level obtained on partially restricted protein intake (1 g/kg/day). A. G., J. B., P. R., and B. S. are intermediate MSUD patients.  

Intermediate Maple Syrup Urine Disease 955
Philadelphia, PA). S.B. is a classic MSUD patient provided by Dr. Lisa Dahl (University of Minnesota Medical Center, Minneapolis, MN), Classic MSUD fetal fibroblasts, A-1, were obtained from Dr. Rivka Carmi (Saroka Medical Center, Beer Sheva, Israel). Lymphoblasts were grown in RPMI-1640 medium containing 15% heat-inactivated fetal calf serum as described previously (8).

Single-stranded conformational polymorphism (SSCP) analysis. All 9 exons of the human Elα gene were amplified by PCR using primers for the flanking intronic sequences (12). The PCR reaction was carried out in Tris-HCl pH 9.0 (10 mM), MgCl₂ (1 mM), KCl (50 mM), 0.1% Triton X-100, dNTPs (0.2 μM each), Taq DNA polymerase (2.5 U) and 1 μM of each sense and antisense primer. To the reaction mixture, 10 μl of 32P-dCTP and 200 ng of genomic DNA as template was added, and the reaction cycled 35 times at 94°C for 30 s, 55°C for 30 s, and 72°C for 1 min. 3 μl of 32P-labeled PCR product were diluted with 27 μl of a solution containing 95% formamide, 20 mM EDTA, 0.05% bromophenol blue, 0.05% xylene cyanol FF and 37 mM methyl mercury hydroxide. Samples were then heated at 100°C for 2 min and chilled on ice. Electrophoresis with 3 μl per lane of each sample applied was carried out on a 0.5× MDE™ gel (J. T. Baker Inc., Phillipsburg, NJ) at constant 6 watts for 18–20 h in 1× TBE buffer. The gels were dried on filter paper and exposed to Kodak X-OMAT film.

Expression and site-directed mutagenesis of Elα cDNA. The construction of the EBO vector for normal human Elα and methods for transient expression and selection of transfected cells have been previously described (8). The EBO-pLpp parental plasmid (11) contains OriP as the origin of replication. The plasmid also harbors the EBNA-1 sequence encoding Epstein-Barr virus nuclear antigen and the hygroycin phosphotransferase sequence that confers antibiotic resistance. The presence of OriP and EBNA-1 sequences allows efficient episomal replication of the plasmid in Epstein-Barr virus transformed lymphoblastoid cells. Nucleotide changes were carried out using the Altered Site™ in vitro mutagenesis system from Promega (Madison, WI). The chromic E. coli cDNA containing the bovine mitochondrial targeting and the mature human sequences (8) was cloned into pAlter-1 vector, which contained a mutation in the ampicillin-resistant gene rendering the transformed cell susceptible to the antibiotic. Single strand DNA was prepared from the pAlter-hE1a plasmid. Mutagenic oligonucleotides containing the mutation and the repair oligonucleotide for the ampicillin-resistant gene were annealed simultaneously to the single stranded DNA. T4 DNA polymerase and ligase were added to synthesize an ampicillin-resistant mutant strand. After two rounds of ampicillin selection, first in the repair minus strain of E. coli (BHM71–18 mut S) then in JM-109 cells, colonies were picked for plasmid DNA preparation. DNA sequencing was performed to confirm the mutation. DNA fragment containing the mutation were excised from pAlter vector by restriction enzyme digestion and ligated into the EBO expression vector (8).

Construction of pHisT-E1a prokaryotic expression vector. The 5′ portion of the mature human Elα cDNA sequence was amplified from the pMAL-c2b-E1α expression vector (9) using an internal 22-mer antisense primer with sequence 5′-GTAACAGATGTCGACCTGGTT-3′, and a 49-mer sense primer with sequence 5′-GGTCTTACGTCTGGAGAATCTTTATTTtcaatcatctctggatgacaagc-3′ to yield a 601-bp product. The sense primer adds exogenous sequence (shown in upper case) to the 5′ terminus of the mature Elα open-reading frame (shown in lower case). This exogenous sequence includes an XbaI restriction site (shown in bold) followed by sequence encoding the first six amino acids specific for the tobacco etch virus (TEV) protease cleavage (shown underlined). The seventh required amino acid for the TEV protease cleavage is supplied by the amino-terminal serine of the mature Elα sequence.

To generate the pHisT-E1α expression vector, the 601-bp amplification product was cut with XbaI and NarI to yield a 454-bp fragment encoding the TEV cleavage site and the 5′ portion of the Elα open-reading frame. The peptide-hE1α expression vector (8) was cleaved with NarI and Xhol to yield a 1064-bp fragment that encodes the 3′ portion of the mature Elα open-reading frame. Both fragments were ligated into the pTrcHisB expression vector (Invitrogen) digested with Nhel and Xhol to yield the pHisT-E1α expression vector. To generate the pHisT-E1α expression vector, a BamHI–Scal fragment (2,555 bp) comprising the trc promoter and the mature human Elα open-reading frame was isolated from expression vector pKK-hE12 (13) and ligated into the corresponding sites in the host pHisT-E1α expression vector, yielding the pHisT-E1α expression vector. Mutant Elα variants of the HisT-hE1 expression vector were constructed identically, except for the substitution of 1064-bp NarI–Xhol fragments isolated from variant pEBO-hE1α plasmids harboring the desired Elα mutation.

Pulse-chase labeling for kinetics of Elα and E1β assembly. E. coli strain CG-712 and the plasmid pGroESL (for overexpression of chaperonins GroEL and GroES) (14) were received as kind gifts from Dr. Anthony Gateman of DuPont Experimental Station (Wilmington, DE). CG-712 cells containing the pGroESL plasmid were transformed with pHisT-hE1 expression vectors carrying the normal mature Elβ cDNA and either normal or mutant His-tagged mature Elα cDNA sequences (15). Cells were grown at 42°C to an O.D.₆₀₀ of 0.80 in C-broth minimal media (16) supplemented with 40 μM TTP, 50 μg/ml carbenicillin, and 50 μg/ml chloramphenicol. Cells were pelleted and resuspended in one-fifth original volume of the same media without antibiotics, and allowed to recover with shaking for 5 min at 37°C. Cells were subsequently induced with 2 mM isopropyl thiogalactoside (IPTG) for 5 min, pulsed with 50 μCi/ml of ³⁵S-Cys/³⁵S-Met (ICN Radiochemicals, Costa Mesa, CA) for 1 min, and chased with three volumes of the same media (without antibiotics) supplemented with 8 mg/ml each of nonradioactive l-cysteine and l-methionine. At specified time points following the chase, cell samples (1.8 ml) were taken and quickly frozen in liquid N₂. Thawed samples were lysed by sonication, and supernatants after microcentrifugation were treated batchwise with an excess (15 μl) of Ni²⁺-NTA (nitrilotriacetic acid) resin from Qiagen (Chatsworth, CA). The resin was washed batchwise three times (total volume: 2.4 ml) with 15 mM imidazole in 100 mM potassium phosphate (pH 7.5) containing 2 mM MgCl₂, 0.1 mM EDTA, 0.1 mM EGTA, 0.2 mM TTP and 2 mM mercaptoethanol. Bound (His)₆-tagged Elα and assembled untagged E1β polypeptides were eluted with 30 μl of Laemmli SDS-sample buffer (17) containing 50 mM EDTA. Eluted labeled polypeptides were analyzed by SDS-PAGE and fluorography.

Other procedures. The amplification of genomic DNA, the flanking intronic primers, the methods for subcloning and sequencing techniques used in this study were previously described (12, 18). Northern and Western blotting were performed as described elsewhere (8, 18, 19). Assays of decarboxylation rates using α-keto-[¹⁴C]isovalerate were performed on intact fibroblasts and transfected and transected lymphoblasts as previously described (10). The activity of recombinant E1 was assayed radiochemically using α-keto-[¹⁴C]isovalerate as a substrate and 2,6-dichlorophenolindophenol as an artificial electron acceptor (10).

Results

Clinical phenotype of intermediate MSUD. As described in Methods, the patients studied in the present report are all of Hispanic-Mexican origin. Their clinical phenotype conforms to that accepted as intermediate MSUD. The patients presented 7–22 mo after birth for evaluation of developmental delay and a mild seizure disorder (Table I). The developmental status of the patients showed significant retardation when their achievement level was compared to their age, (Table I, right column). MSUD was not suspected until a metabolic screen revealed marked elevation of the BCAAs and BCKAs and the presence of alloisoleucine. Plasma leucine in the four patients ranged from 1,218–3,347 μM as also shown in Table I. Dietary restriction of BCAAs ameliorates further neurological impairment, and allowed developmental progress to occur (See Methods).

To confirm that the above intermediate MSUD patients are deficient in the decarboxylation of the α-keto acids, intact cell

Intact cells from fibroblast cultures were assayed in triplicate at 2 mM for pyruvate and α-ketoisovalerate (KIV). Specific radioactivities were 1,275 and 750 cpm/nmol for [1-14C]pyruvate and α-keto[1-14C]-isovalerate, respectively. For each assay, 1 x 10^8 cells (0.25 mg of protein) were incubated at 37°C for 10 min with labeled pyruvate and 80 min with α-ketoisovalerate. A. G., J. B., P. R., and B. S. are intermediate MSUD patients.

assays with cultured fibroblasts were carried out. Table II shows that three of the intermediate patients (A.G., J.B., and P.R.) had 4 to 5.6% of residual activity compared to normal. These activities are in the range reported for other intermediate MSUD patients (1, 2). The fourth patient, B.S., had no detectable activity similar to classic MSUD. The decarboxylation rate with pyruvate was normal in all patients and served as a control for cell viability (Table II). The intact cell results establish that the metabolic block in the intermediate MSUD patients is at the decarboxylation of BCKAs.

Western and Northern blot analysis of normal and mutant cells. Since the BCK AD complex is a heteromultimeric protein, it was necessary to identify which subunit was affected in these individuals with MSUD. Western blotting was carried out using lysates prepared from normal and MSUD fibroblasts. Fig. 1 (lower panel) shows that the E1α subunit is markedly reduced in cells from three intermediate patients A.G., J.B., and P.R. compared with normal. The E1α subunit is barely detectable in the fourth intermediate patient B.S. and a classic patient L.C. In contrast, the E1α subunit is present in normal amounts in another classic MSUD patient S.B. The E2 subunit (Fig. 1, upper panel) is present in normal amounts in all MSUD patients except S.B. The results establish that S.B. is affected at the E2 locus. On the other hand, the decreased abundance of E1α subunit in the five MSUD patients studied (A.G., J.B., P.R., B.S., L.C., H.H., and B.F.) only indicate that either E1α or E1β locus is affected. It has been previously shown by Western blotting that reduced level of either of the two subunits of E1 (E1α or E1β) caused by a mutation reduces the level of the other normal subunit (20–22).

Northern blotting was performed using poly(A)^+ RNA prepared from normal, a classic MSUD patient from Israel (A-1) and the four intermediate MSUD subjects (B.S., P.R., A.G. and J.B.) from Mexico. The E1α mRNA is present in normal amounts in the four intermediate MSUD patients (lanes 1–6, Fig. 2, upper panel), and is absent in the classic MSUD patient (lane 2). The E1β mRNA is present in all MSUD patients (Fig. 2, lower panel). The reduced signal of E1β mRNA in normal (lane 1, lower panel) was due to the lower amount of poly(A)^+ RNA applied (1.5 μg) compared with the other lanes (5 μg). The results show that the mutation of the E1α or E1β locus did not affect transcription and stability of either mRNA in the intermediate MSUD, and that reduction in the immunoreactive E1α subunit is a posttranscriptional event.

Identification of mutations in intermediate MSUD. Previously we identified an 8-bp deletion in exon 7 of the E1α gene of an MSUD patient GM-649, which abolishes a Smal restriction site (18). This change in restriction pattern was used to screen other MSUD patients. Exon 7 was amplified from genomic DNA of 35 known MSUD subjects and digested with Smal. The digested samples were analyzed on 2% agarose gels as shown in Fig. 3. Undigested amplified exon 7 from a normal subject was 240-bp in size (lane 2). Digestion of the normal amplified genomic DNA with Smal produced two smaller 169- and 71-bp fragments (lane 3). Digestion of the amplified exon 7 from GM-649, who is heterozygous for 8-bp deletion, resulted...
in three fragments (lane 4). An uncut 240-bp fragment is caused by the absence of the Smal site secondary to the 8-bp deletion. The other two smaller species are contributed by the other allele, which contains a normal Smal site in exon 7. Interestingly, amplified DNA from exon 7 of three of the Mexican patients with intermediate MSUD (A.G., J.B., and P.R.) was not cut by Smal (lanes 5–7). Two other MSUD patients of Mexican origin, B.S. (intermediate) and P.V. (classic), shows a normal restriction pattern of 169- and 71-bp fragments (lanes 8 and 9), which was also observed in 29 other MSUD patients (data not shown).

The absence of the Smal site in exon 7 in these intermediate patients, A.G., J.B., and P.R., led us to initially speculate that these patients were homozygous for the 8-bp deletion at the E1α locus. To confirm this, amplified exon 7 from these patients was subcloned into Bluescript plasmid and sequenced. To our surprise, a homozygous G to A transition at base 895 of the E1α gene (12), instead of an 8-bp deletion, was found at the Smal site (Fig. 4). The G to A conversion accounts for the abolishment of the Smal site, and a Gly-245 to Arg substitution (G245R) in the E1α subunit.

Since intermediate patient B.S. showed a normal Smal digestion pattern, the mutation in this patient does not involve this restriction site. To determine the mutation in B.S., all nine exons of the E1α gene were amplified using flanking intron primers. Each amplified exon was subjected to analysis by single-stranded conformational polymorphism (SSCP) (23). As shown in Fig. 5 (the upper bands), amplified exon 9 from B.S. (lane 2) has a distinct shift in mobility, compared to a normal (lane 1) and two other classic MSUD patients B.F. (lane 3) and H.H. (lane 4) that also had normal mobility. Lanes 5 and 6 are two patients (K.U. and B.A.), who are heterozygous for the Y393N mutation in exon 9, which resulted in a doublet in the upper band as indicated by the arrows.

The results of SSCP indicated that intermediate patient B.S. is homozygous for a mutation in exon 9. Direct sequencing of amplified exon 9 using 32P-end labeled primers was carried out with a normal and three MSUD patients (B.S., B.F., and K.U.). To facilitate detection of the mutation, the sequencing samples were applied to a polyacrylamide gel according to the four nucleotide groups A, C, G and T (Fig. 6). Intermediate patient B.S. shows a distinct homozygous T to G transversion at base 1253 of the E1α gene (12) (see column G and T). The mutation results in a Phe-364 to Cys substitution (F364C) in the E1α subunit.

**Characterization of the G245R and F364C mutations.** The
G245R and F364C mutations were introduced into the normal Ela cDNA by site-directed mutagenesis, and the mutations were confirmed by DNA sequencing. The entire Ela cDNA containing either mutation was inserted into the EBO expression vector for transient expression studies. The plasmids carrying the normal and the mutant Ela cDNAs were transfected into Ela deficient lymphoblasts from a Mennonite classic MSUD patient (LMK). LMK cells are homozygous for the Y393N substitution in the Ela subunit (24). Intact untransfected and transfected lymphoblasts were used to measure the rate of decarboxylation of α-keto [1-14C] isovalerate. Fig. 7 shows that untransfected normal lymphoblasts have substantial (100%) enzyme activity, (lane 1), and that LMK cells transfected with the EBO vector without insert (lane 2) exhibited trace or no decarboxylase activity. Transfection of LMK cells with vector containing the normal Ela cDNA (lane 3) restored decarboxylase activity to 72% of normal. LMK cells transfected with vector containing the G245R mutation in Ela cDNA produced a slight but reproducible (5%) decarboxylation of the α-keto acid. Transfection of LMK cells with vector containing the Ela cDNA with the F364C substitution was unable to dekcarboxylate α-ketoisovalerate. The results establish that the G245R and F364C alterations produce defective Ela polypeptides, and are the cause of the intermediate MSUD phenotype.

Lysates prepared from untransfected normal lymphoblasts and from transfected LMK lymphoblasts were analyzed by Western blotting (Fig. 8). Specific antibodies against either Ela or Elβ subunits were used as probes. LMK cells untransfected or transfected with EBO vectors without inserts showed reduced levels of the Ela subunit, compared to normal untransfected cells (Fig. 8, upper panel). LMK cells transfected with vector harboring normal Ela cDNA increased the Ela subunit to a level similar to normal, but with the appearance of a smaller proteolytic fragment (Ela*). (Fig. 8, upper panel). A similar increase in Ela subunit was observed in LMK cells transfected with the five mutant Ela cDNAs (Fig. 8, upper panel). G245R and F364C in Ela are the subjects of the current study. N222S and R220W in Ela encoded by exon 6 are mutations in the putative TFP-binding pocket. T265R in Ela encoded by exon 7 is a mutation in the putative subunit interaction region (Chuang, J. L., D. T. Chuang, and R. P. Cox, unpublished results). The LMK cells transfected with vector having a normal, N222S or R220W Ela cDNAs restored the Elβ subunit to approximately half the normal level (Fig. 8, lower panel). The results indicates that mutant Ela subunits containing the N222S or R220W mutation are able to assemble with endogenous Elβ, similar to normal Elα. The mutant El proteins containing these mutations have markedly reduced El enzymatic activity (data not shown). LMK cells transfected or with the EBO vector without inserts showed trace amounts of the Elβ subunit (Fig. 8, lower panel). Transfection of LMK cells with vector containing the G245R Ela cDNA restored Elα to ~ 20–30% of that transfected with normal Ela cDNA. In LMK cells transfected with the F364C and T265R cDNA, the Elβ subunit remained in trace amounts, indicating the absence of assembly between the mutant Elα and normal Elβ (Fig. 8, lower panel).

Altered kinetics of El assembly caused by G245R and F364C mutations. The reduced ability of transfected G245R...
The lysates T265R, Figure 8. Western blotting of lysates from vector without insert or carrying normal, N222S, R220W, G245R, T265R, or F364C mutant Elα cDNAs (see text for these mutations). The lysates were prepared from untransfected normal and transfected cell and were subjected to SDS-PAGE, with each lane containing 200 μg protein. Proteins were electrotransferred to polyvinylidene difluoride membranes. The filters were probed with either Elα (upper panel) or Elβ (lower panel) antibodies radiolabeled by coupling with 125I-protein A. Elα represents proteolytic products.

and F364C Elα to restore Elβ in LMK cells compared with normal Elα, strongly suggests that, in addition to causing enzyme dysfunction, these mutations impair El assembly. To investigate the kinetics of Elα and Elβ assembly, we have developed a method for pulse-chase labeling of El subunits in an E. coli host. ES4 E. coli cells were doubly transformed with a His-tagged El expression vector carrying either normal or mutant His-tagged Elα cDNA and normal untagged Elβ cDNA, as well as a second vector pGroESL that over-expresses bacterial chaperonin proteins GroEL and GroES. The cells were heat-shocked at 42°C for 4 h, followed by induction at 37°C with IPTG for 5 min. The cells were pulsed with [35S]cysteine/ [35S]methionine for 1 min and chased with the corresponding nonradioactive amino acids. Samples were taken at different intervals from 2 min to 120 min, and lysates purified by Ni²⁺-NTA affinity chromatography. The eluted radioactive peptides were analyzed by SDS-PAGE and autoradiograms obtained by fluorography. Since Elβ is untagged, its copurification with His-tagged Elα is an indication of assembly of the two polypeptides. Fig. 9 A shows that the assembly of radioactively labeled Elβ with labeled normal Elα occurs as early as 10 min after the chase, approaching a plateau in 40 min. The level of the normal labeled His-tagged Elα remains relatively constant during the 2 h chase. The assembly of normal Elβ with the labeled G245R Elα appears to be slower than normal Elα. The level of associated Elβ is clearly much lower than that observed in the normal Elα, and reached a plateau at 60 min after the chase (Fig. 9 B). In contrast, there was no significant assembly of labeled Elβ with His-tagged mutant F364C Elα during the 2 h chase. This was indicated by the absence of the copurified Elβ, while the signal of His-tagged Elα remained relatively constant (Fig. 9 C). These results indicate that both G245R and F364C mutations reduce the rate of assembly of mutant Elα with normal Elβ.

Reduced or undetectable activity of mutant El proteins. Prolonged growth of E. coli with IPTG induction at 37°C for 15 h resulted in the production of reduced but significant amounts of assembled mutant His-tagged El proteins carrying G245R or F364C mutations in Elα, compared with normal. Both normal and mutant His-tagged El proteins were purified by Ni²⁺-NTA affinity column and eluted with a 15 to 250 mM imidazole gradient (pH 7.5). The final yield was 50 mg/l culture for normal E1 protein, 8 mg/l culture for G245R mutant E1 and 6 mg/l culture for F364C mutant E1. Activity of normal and mutant El proteins was assayed by a radiochemical method using α-keto[1-¹⁴C]isovalerate as a substrate and 2,6-dichloro-
phenolindolphenol as an artificial electron acceptor. Recombinant normal E1 protein showed specific activity of 87.3±13.7 nmol CO₂/min/mg protein (n = 3) and G245R mutant E1 protein exhibited specific activity of 2.32 ± 0.14 nmol CO₂/min/mg protein (n = 3). F364C mutant E1 protein had no measurable activity. The specific activity of G245R mutant E1 protein was 2.7% of normal.

Discussion

This is the first detailed molecular and biochemical characterization of intermediate MSUD. Previous studies were predominantly of the classic form of the disease because of its prevalence among MSUD patients and the severity of its presentation. On the other hand, intermediate MSUD is milder and often later in presentation, and as a result is understudied. It is of interest that BCKAD activity of intermediate patient B.S. is at the level of classic MSUD, but her phenotype is distinctly of the intermediate type. Other studies have also noted a poor correlation of residual BCKAD complex activity with the clinical phenotype (25). These findings suggest that the individual’s genotype may modulate the severity of disease. Alternatively, the enzyme activity in a patient’s hepatocytes may not be accurately reflected in fibroblast or lymphoblast cultures. The BCKAD complex is 30–50% dephosphorylated or active in fibroblasts (10, 26), whereas it is nearly 100% dephosphorylated or active in the liver (27). In addition, activities of the totally dephosphorylated BCKAD complex in several tissues (liver, kidney, and heart) are higher than in fibroblasts (28). The presence of residual activity in various tissues of intermediate MSUD patients may be significant under certain physiological conditions to ameliorate clinical manifestations. For example, in response to changes in dietary protein or increased catabolism (e.g., starvation), levels of hepatic BCKAD subunits increase a few fold (Chinsky, J. M., unpublished results) (29). Unfortunately, tissues other than fibroblasts and lymphoblasts from these intermediate patients were unavailable for testing. It should be pointed out that patient B.S. had the most severe neurological damage and the highest plasma leucine levels of the four intermediate MSUD patients described. However, she was also diagnosed later than the other three intermediate patients. The results underscore the importance of newborn screening and early dietary therapy for intermediate MSUD.

It is noteworthy that all of the three intermediate MSUD patients that are homozygous for the G245R mutation are of Hispanic-Mexican origin. Heterozygosity in MSUD is relatively rare except for the Y393N Mennonite mutation where the Founder effect is responsible (30). Analysis of 31 non-Mexican patients showed that these subjects did not have the G245R mutation. Although relatedness and consanguinity were denied by their families, two of the intermediate patients, who are homozygous for the G245R mutation, were from the Monterey area of Mexico and the third was from Southern Mexico. It is possible that the three apparently unrelated families inherited this mutation from a common ancestor. More intermediate MSUD families of Hispanic origin need to be studied to determine the prevalence of the G245R allele in the Mexican population. There is a high frequency of MSUD in Spain (1/12,000 to 1/50,000) (31) compared with the estimated worldwide prevalence of 1/180,000 (32). The increased incidence of MSUD in Spain suggests a possible ethnic source for these mutations. The fourth Mexican patient is homozygous for the F364C mutation. She is the progeny of a 14-yr-old primigravida, so the significance of this homozygosity is uncertain.

Functional analysis of MSUD mutations cannot be carried out by overexpression of the affected subunit in a normal host, where multiple copies of all six distinct polypeptides are present. In the present study, we used an E1α-deficient lymphoblasts host from a Mennonite patient homozygous for the Y393N mutation in the E1α subunit (24). Transfection with a replication-competent EBO vector carrying the full-length normal E1α cDNA resulted in overexpression of the E1α subunit. However, only a near normal range of decarboxylation activity is restored in the host cells (Fig. 7). The data suggest that the assembly of recombinant normal E1α with endogenous normal E1β subunits is limiting as will be discussed later. A partial (5%) restoration of decarboxylation activity was observed, when the G245R E1α cDNA was transfected into LMK cells. This rate is similar to the residual (4.0–5.6%) activity in cultured fibroblasts from the intermediate MSUD patients, who are homozygous for this mutation. The lack of restoration of decarboxylation activity by transfection with F364C E1α cDNA also agrees with the absence of decarboxylation measured with cultured fibroblasts from the homozygous patient B.S. The concordance between the transfection results and assays of patient’s cultured fibroblasts indicates the fidelity of the EBO expression system.

The LMK host cells used in transfection studies contain reduced levels of the Y393N mutant E1α subunit and trace amounts of the normal E1β subunit (8). The homozygous Y393N E1α mutation was shown to impede assembly of that subunit with normal E1β subunits. Unassembled E1α and in particular E1β subunits are not stable and are degraded in cells (20, 22). It is perplexing that transfection of LMK cells with normal E1α cDNA restores the E1β subunit to only 50% of normal level (Fig. 8). Since the EBO vector overexpresses normal E1α subunits, one would expect that the E1β level is restored to normal through assembly with recombinant E1α. Competition between the endogenous Y393N and the transfected normal E1α subunits for assembly with E1β is unlikely because the host mutant E1α subunit is assembly-incompetent. A plausible explanation is that only a portion of the transfected normal E1α subunit in the LMK cell is properly folded, and capable of assembly with E1β. Recent studies have firmly established that molecular chaperones, most of them heat-shock proteins (Hsp), play an essential role in the biogenesis of mitochondrial proteins (33). In mitochondria of transfected LMK cells, chaperone proteins Hsp60 and Hsp10 may be limiting, resulting in reduced levels of assembly-competent recombinant E1α subunits. The current model for chaperone-mediated mitochondrial import is that the nascent polypeptides, while still associated with the ribosome, bind to the cytosolic Hsp70 to maintain the unfolded and import-competent state. Once imported into the mitochondrial matrix, the unfolded mature polypeptide initially interacts with mitochondrial Hsp70, and is then transferred to the Hsp60/Hsp10 complex of this organelle. The latter complex provides a scaffold for proper folding of the mature polypeptide to occur through multiple cycles of ATP hydrolysis-dependent reactions (33, 34).

The pulse-chase labeling studies in E. coli represents a novel approach to measure the initial rates of E1α and E1β subunit assembly. Development of this method is based on the thesis that the bacterial cells are analogous to the mitochondrial matrix in the folding and assembly of mature mitochondrial polypeptides. The molecular chaperones that participate in the biogene-
sis of mitochondrial proteins are conserved in *E. coli* (33). We have shown previously that overexpression of the bacterial chaperones GroEL and GroES, which are homologues of Hsp60 and Hsp10, respectively, in ES61 *E. coli* (CG-712) increased the specific activity of El1 by 500-fold (15). Expression and assembly of El1 in wild-type *E. coli* is very low in the absence of overexpressed chaperones (9). The overproduction of GroEL and GroES was achieved through cotransformation with the pGroESL plasmid. The latter plasmid encodes these chaperones under the regulation of a heat-shock sensitive element and an IPTG-inducible promoter. The double-transformation overexpression is adapted in the pulse-chase labeling studies with the pHIS7·hEl1 plasmid that encodes both His-tagged El1α and untagged El1β as the second vector. The bacterial overexpression system may not completely duplicate the situation in mammalian cells. Nonetheless, it offers a useful method to dissect, under efficient ex vivo conditions, the effect of certain natural human mutations on chaperone-mediated folding and assembly of mammalian proteins.

Isolation of the His-tagged El1α/untagged El1β subunit complex by nickel affinity column chromatography represents the association of the pulse-labeled nascent chains (Fig. 9). No attempt was made to distinguish assembly intermediates from the final αβ2 heterotetramers. Using this optimal overexpression system in *E. coli*, we were able to demonstrate altered kinetics of El1 assembly in intermediate MSUD. The slower than normal kinetics observed with the G245R mutation confirm the partial assembly defect deduced from the transfection studies. The absence of significant assembly of the His-tagged mutant F364C El1α subunit with the normal El1β subunit during the 2 h chase supports the severe assembly incompetence associated with this mutation. The crystal structure of El1 has not been determined, but the conserved Gly-245 is in the putative subunit interaction region based on sequence alignment of El1α subunits (35). Chou-Fasman prediction (36) indicates that Gly-245 in the El1α subunit occurs at a turn preceding a Pro at position 246. The G245R substitution may alter the conformation of the turn, thereby adversely affecting the binding of the El1α to El1β subunit. Phe-364 is situated in the carboxy-terminal region encoded by exon 9 of the El1α gene. This segment is also highly conserved between El1α subunits of different α-keto acid dehydrogenase complexes, however, no function has been assigned to this carboxy-terminal region. We have shown that, in addition to F364C, two other known mutations Y393N (9, 24) and Y368C (18) encoded by exon 9 were also defective in El1 assembly. These findings strongly suggest that the exon 9 encoded carboxy-terminal residues are critical for El1α and El1β subunit interaction.

Finally, sustained growth (15 h) of transformed *E. coli* with IPTG induction results in production of reduced but significant amounts of G245R and F364C mutant El1 proteins compared with normal. The data indicate that the individual mutant El1α and normal El1β subunits are stable in *E. coli* cotransformed with chaperonins GroEL and GroES, and eventually assemble into mutant heterotetramers. The low or undetectable activity of recombinant G245R and F354C mutant El1 proteins provides direct evidence that both mutations in El1α disrupt the catalytic function of the assembled heterotetramers, in addition to the slow rates of assembly. The impaired El1 activity is consistent with the reduced or absent decarboxylation of BCKA observed in patients’ fibroblasts (Table II) and in the transfection studies (Fig. 7). Moreover, the deficiency of El1 activity is apparently responsible for dysfunction of the BCKA complex in the intermediate MSUD patients.
