The study of human cardiac tissue development is hampered by the lack of a suitable in vitro model. We describe the phenotypic properties of cardiomyocytes derived from human embryonic stem (ES) cells. Human ES cells were cultivated in suspension and plated to form aggregates termed embryoid bodies (EBs). Spontaneously contracting areas appeared in 8.1% of the EBs. Cells from the spontaneously contracting areas within EBs were stained positively with anti–cardiac myosin heavy chain, anti–β-actinin, anti-desmin, anti–cardiac troponin I (anti-cTnI), and anti-ANP antibodies. Electron microscopy revealed varying degrees of myofibrillar organization, consistent with early-stage cardiomyocytes. RT-PCR studies demonstrated the expression of several cardiac-specific genes and transcription factors. Extracellular electrograms were characterized by a sharp component lasting 30 ± 25 milliseconds, followed by a slow component of 347 ± 120 milliseconds. Intracellular Ca2+ transients displayed a sharp rise lasting 130 ± 27 milliseconds and a relaxation component lasting 200–300 milliseconds. Positive and negative chronotropic effects were induced by application of isoproterenol and carbamylcholine, respectively. In conclusion, the human ES cell–derived cardiomyocytes displayed structural and functional properties of early-stage cardiomyocytes. Establishment of this unique differentiation system may have significant impact on the study of early human cardiac differentiation, functional genomics, pharmacological testing, cell therapy, and tissue engineering. J. Clin. Invest. 108:407–414 (2001). DOI:10.1172/JCI200112131.

Introduction
The study of early human cardiomyocyte development is hampered by the lack of a suitable model. Hence, valuable information regarding the differentiation of early human cardiac precursor cells, the development of excitability, excitation-contraction coupling, and the molecular signals involved in these processes is largely lacking. In addition, adult cardiomyocytes permanently withdraw from the cell cycle and therefore cannot regenerate. Hence, significant loss of cardiomyocytes is irreversible and leads to the development of progressive heart failure. A potential novel therapeutic approach for this situation is to increase the number of functional cardiomyocytes within the depressed region by implantation of myogenic cells. Recent studies demonstrated that fetal cardiomyocytes could survive in infarcted tissue, differentiate, and possibly improve cardiac performance (1, 2). Given that human fetal tissue cannot be obtained in sufficient quantities in the clinical setting, a new source of human cardiomyocytes is sorely needed.

Embryonic stem (ES) cells are continuously growing stem cell lines of embryonic origin, first isolated from the inner cell mass of mouse blastocysts (3). These unique cells are characterized by their capacity to proliferate in an undifferentiated state for a prolonged period in culture, and by their ability to differentiate into every tissue type in the body. The advent of murine ES cells has provided important insights into the early steps of development of excitability in the mammalian heart, including patterns of gene expression, myofibrillogenesis, ion channel development and function, receptor development, and calcium handling (4–9).
Given the outstanding potential demonstrated by mouse ES cells, it is not surprising that much effort has been spent on the development of human ES cell lines. This quest ended recently when two groups described the generation of human blastocyst-derived ES cell lines (10, 11). The human ES cells were demonstrated to fulfill all the criteria defining ES cells, namely, derivation from the pre- or peri-implantation embryo, prolonged undifferentiated proliferation under special conditions, and the capacity to form derivatives of all three germ layers. Hence, when cultured with mitotically inactivated mouse embryonic fibroblast (MEF) feeder layer, they could be maintained in the undifferentiated state for prolonged periods. Further studies revealed that when human ES cells were allowed to spontaneously differentiate, they formed embryoid bodies (EBs) containing derivatives of all three germ layers (12). More recently, the effects of different growth factors on differentiation into various lineages were tested in this system (13).

In this report, we describe the use of human ES cells as a reproducible differentiation system for human cardiomyocytes. Using this system, spontaneously contracting foci were, for the first time to our knowledge, demonstrated to have ultrastructural and functional properties consistent with a cardiomyocytic phenotype.

Methods

ES cell preparation and production of EBs. Human undifferentiated ES cells of the single-cell clone H9.2 (14) were grown on mitotically inactivated (mitomycin C) MEF feeder layer in culture medium as described previously (10). The culture medium consisted of 80% knockout DMEM (no-pyruvate, high-glucose formulation; Life Technologies Inc., Rockville, Maryland, USA) supplemented with 20% FBS (HyClone, Logan, Utah, USA), 1 mM L-glutamine, 0.1 mM mercaptoethanol, and 1% nonessential amino acid stock (all from Life Technologies Inc.).

To induce differentiation, ES cells were dispersed to small clumps (three to 20 cells) using collagenase IV (Life Technologies Inc.; 1 mg/ml for 20 minutes). The cells were then transferred to plastic Petri dishes (Miniplast, Ein Shemer, Israel), at a cell density of about 5 × 10^6 cells in a 58-mm dish, where they were cultured in suspension for 7–10 days. During this stage, the cells aggregated to form EBs, which were then plated on 0.1% gelatin-coated culture dishes, where they are observed for the appearance of spontaneous contractions. After 10 days in suspension, EBs are grown on top of the MEF feeder layer (left). To induce differentiation, cells are transferred to suspension, where they aggregate to form EBs (middle). After 10 days in suspension, EBs are plated on gelatin-coated culture dishes, where they are observed for the appearance of spontaneous contractions (right). (b) Photomicrographs depicting the just-mentioned three stages: ES colony (left), EBs in suspension (middle), and a contracting area in the outgrowth on an EB (right, arrow).

Figure 1

Stages in EB production and differentiation. (a) Schematic of the three stages in human ES cell differentiation. Initially, the ES colonies are grown on top of the MEF feeder layer (left). To induce differentiation, cells are transferred to suspension, where they aggregate to form EBs (middle). After 10 days in suspension, EBs are plated on gelatin-coated culture dishes, where they are observed for the appearance of spontaneous contractions (right). (b) Photomicrographs depicting the just-mentioned three stages: ES colony (left), EBs in suspension (middle), and a contracting area in the outgrowth on an EB (right, arrow).
1:250 (all from Chemicon International Inc., Temecula, California, USA). Staining of sarcomeric α-actinin and nebulin was performed using anti-sarcomeric α-actinin mAb's at a dilution of 1:800 and anti-nebulin mAb's at a dilution of 1:200 (both from Sigma Chemical Co.), respectively. After three washes with PBS, cells were incubated with secondary donkey anti-mouse, FITC-conjugated IgG antibodies, absorbed against human tissue for myosin heavy chain, desmin, and troponin I staining, or rhodamine-conjugated anti-rabbit IgG antibodies for α-actinin, ANP, and nebulin staining (both from Chemicon International) at a dilution of 1:100 for 1 hour at room temperature. Preparations were examined using fluorescence microscopy. Dispersed cells isolated from noncontracting EBs served as controls.

RT-PCR. Total RNA from undifferentiated ES cells and contracting EBs was extracted using TRI reagent kit (Sigma Chemical Co.) according to the manufacturer’s instructions. cDNA was synthesized from 1 µg total RNA using SuperScript II reverse transcriptase (Life Technologies Inc.). cDNA samples were subjected to PCR amplification with primers selective for human cardiac genes. The PCR primers and the reaction conditions used are described in Table 1. The PCR products were size fractionated by 2% agarose gel electrophoresis.

Electron microscopy. For transmission electron microscopy, the spontaneously contracting areas were mechanically dissected. The tissues were fixed in 3% glutaraldehyde in 0.1 M cacodylate buffer (pH 7.4) at 4°C for 24 hours, postfixed in 1% OsO4 in the same buffer for 1 hour, dehydrated in graded ethanols, and embedded in Epon 812. Thin (60–90 nm) sections were used for ultrastructural evaluation using a JEOL USA Inc. 100 SX transmission electron microscope (Peabody, Massachusetts, USA) operating at 80 kV.

hANP, human ANP; Oct-4, octamer-binding protein 4. ARef. 15. BRef. 16. CRef. 17. DRef. 12.
sey, USA) as described previously (19). Briefly, two different wavelengths (340 and 380 nm) were used for excitation, and the emitted fluorescence (510 nm) was collected and detected by a photomultiplier tube (710 PMT, photomultiplier detection system; Photon Technology International). Raw data were stored for off-line analysis by the FeliX software (Photon Technology International) as 340 and 380 nm counts and as the ratio $R = F_{340}/F_{380}$. The Savitzky-Golay smoothing algorithm was used to reduce noise level.

Statistical analysis. Data are expressed as mean ± SD. To assess possible chronotropic effects, the average spontaneous beating rate was compared before and after drug application using two-tailed paired Student’s $t$ test. $P$ values less than 0.05 were considered significant.

Results

Human ES cell–derived cardiomyocytes form spontaneously contracting areas. Figure 1b depicts typical examples of ES colonies grown on top of the MEF feeder layer, the formation of EBs during the suspension phase, and an EB containing a contracting area after plating. Rhythmically contracting areas appeared at 4–22 days after plating. Figure 2 illustrates the cumulative percentage of EBs containing contracting areas as a function of the time after plating. Such contracting areas appeared in 153 (8.1%) of the 1,884 EBs studied. At 11–12 days after plating, 50% of the plateau value was reached. The contracting areas usually appeared in the outgrowth of the EB, with a diameter range of 0.2–2 mm, and continued to beat vigorously for up to 5 weeks (the longest period studied). DMSO at a concentration of 0.75% did not cause a major change in the percentage of beating EBs, with 46 of 454 (10.1%) of the EBs demonstrating contracting areas.

Structural analysis. Light microscopy revealed that the contracting areas were composed mainly of relatively small mononuclear cells, 10–30 µm in diameter, with round or rod-shaped morphology. Transmission electron microscopy of these cells revealed mononuclear cells, with parallel arrays of myofibrillar bundles oriented in an irregular manner in some cells (Figure 3a), whereas more mature sarcomeric organization was apparent in others (Figure 3, b and c). The degree of myofibrillar organization varied within different areas of the same cell, among different cells in the same EB, and among different EBs. Nevertheless, in general, a shift from an immature phenotype manifested by disorganized myofibrillar stacks in early stage EBs (Figure 3a) to a more organized sarcomeric structure in later stage EBs (Figure 3, b and c) was noted. In some foci, the formation of early and more developed Z bands could be observed (Figure 3, b and c). The intercalated disc, another cellular structure that characteristically appears during in vivo cardiomyocyte differentiation, was observed in many of the differentiating

Figure 2

EBs. Hence, intercalated discs composed of gap junctions and desmosomes were observed to connect adjacent cells (Figure 3, d and e).

Using immunocytochemistry, the presence of cardiac-specific proteins and their spatial organization were studied in dispersed cells forming contracting EBs. Figure 4a shows positive immunostaining of dispersed myocytes with anti-cardiac α/β-myosin heavy chain mAb’s. Varying degrees of myofibrillar organization were noted among the cells. The staining patterns ranged from cytoplasmic clumps in some cells to non-parallel bundles of elongated fibrillar structures in others. Some of these bundles displayed an early striated pattern (Figure 4b). The contracting myocytes also stained positively with anti-α-actinin mAb’s (Figure 4c), anti-cTnI mAb’s (Figure 4d), and anti-desmin mAb’s (Figure 4e), with different cells demonstrating varying degrees of sarcomeric organization. In addition, the positive staining by anti-ANP (Figure 4f) suggested the presence of cytoplasmic ANP granules. In contrast to the positive staining with cardiac-specific proteins, cells from the contracting areas did not demonstrate nebulin immunoreactivity, confirming the cardiomyocytic, rather than skeletal, nature of the cells.

To determine the percentage of cardiomyocytes in the contracting areas, the regions exhibiting spontaneous contracting activity were microdissected, enzymatically dispersed, and plated at low density to allow identification of individual cells by immunocytochemistry. Using cTnI mAb’s, the percentage of positively stained cells was 29.4%.

**Gene expression studies.** The expression of several cardiac-specific genes was assessed in the human ES cell–derived cardiomyocytes and in undifferentiated ES cells using RT-PCR. As shown in Figure 5, myocytes from contracting EBs expressed the cardiac transcription factors GATA4 and Nkx2.5 as well as the cardiac-specific genes cTnI, cardiac troponin T (cTnT), atrial myosin light chain (MLC-2A), ventricular myosin light chain (MLC-2V), and α-myosin heavy chain. MLC-2A expression was also noted in the undifferentiated ES cells, but was markedly increased in the contracting EBs. Octamer-binding protein 4, a marker of undifferentiated cells, was expressed in the ES cells. This expression significantly declined in the contracting EBs. The housekeeping gene GAPDH served as an internal control.

**Measurements of [Ca^{2+}]_i transients.** [Ca^{2+}]_i transients were measured from spontaneously contracting EBs using fura-2AM (n = 7). The average spontaneous beating rate was 0.9 ± 0.11 Hz. Figure 6a displays typical recordings with an initial rise in systolic [Ca^{2+}]_i and a slower decay. The time to peak systolic [Ca^{2+}]_i is 0.9 ± 0.11 Hz.
averaged 130 ± 27 milliseconds, the time to half-peak relaxation was 143 ± 94 milliseconds, and total transient length was 465 ± 180 milliseconds. In all cases, the [Ca\(^{2+}\)] signals were synchronous with the contraction rate observed microscopically.

Extracellular electrophysiological recordings and chronotropic studies. Extracellular recordings from the contracting areas displayed electrograms consisting of a sharp component with a peak-to-peak amplitude of 630 ± 33 µV lasting 30 ± 25 milliseconds, followed by a slow component of 347 ± 120 milliseconds, representing the depolarization and repolarization processes, respectively (Figure 6b). The average spontaneous beating rate was 94 ± 33 beats per minute (n = 8) and was stable (mean frequency SD of 1.55 beats per minute) during a recording period of 20 minutes in all EBs studied.

Positive and negative chronotropic responses were observed after administration of the β-agonist isoproterenol and the muscarinic agonist carbamylcholine, respectively. Isoproterenol at 10^-6 M significantly increased spontaneous contraction rate to 146% ± 43% of its baseline value (n = 8; P < 0.01). Similarly, the direct adenylate cyclase activator forskolin and the phosphodiesterase inhibitor IBMX increased spontaneous contraction rate to 182% ± 48% (n = 6; P < 0.01) and 152% ± 77% (n = 6; P < 0.05) of its initial value. In contrast, the muscarinic agonist carbamylcholine at 10^-6 M decreased the rate to 78% ± 20% of its initial value (n = 6; P < 0.05). The latter effect was reversed by application of the muscarinic antagonist atropine. All of these responses were prompt, occurring within 90 seconds of drug application.

Discussion
ES cells provide a unique cellular system to study commitment and differentiation of embryonic tissue under in vitro conditions. Cultured as EBs, murine ES cells recapitulate the development of cardiomyocytes from very early cardiac precursor cells to terminally differentiated cells (7). The advent of the murine ES model has thus provided important insights into the early steps of cardiomyogenesis, including the origin, commitment, and differentiation of cardiac cells, patterns of gene expression, myofibrillogenesis, ion channel development and function, and calcium handling (4–9). Nevertheless, there are significant differences between human and murine development, and, for ethical reasons, it is essentially impossible to study the postimplantation human embryo directly.

In this report, we have described a reproducible novel system in which human ES cells differentiate into cardiomyocytic tissue. Our results demonstrate that the spontaneously contracting tissue within the developing EBs contain myocytes portraying structural and functional properties consistent with early-stage cardiac tissue.

Several lines of evidence confirm the cardiomyocytic nature of these cells. Ultrastructural analysis of the differentiating cardiomyocytes showed that these cells were mainly mononuclear and round or rod-shaped, contained different degrees of myofibrillar bundle organization, and exhibited nascent intercalated discs. These myofibrillar structures stained positively with anti-human cardiac myosin heavy chain, anti–α-actinin, anti-desmin, and anti-cTnI mAb’s. The cells, however, did not exhibit immunoreactivity with anti-nebulin mAb’s, a specific skeletal muscle sarcomeric protein shown to be expressed early in skeletal myoblast differentiation (20).

These results are consistent with ultrastructural properties of early-stage cardiomyocytes and with the developmental process of myofibrillar assembly. Previous studies demonstrated that during in vivo cardiomyogenesis, myofibrils are initially distributed in sparse, irregular myofibrillar arrays, which gradually mature into parallel arrays of myofibrils and ultimately align into densely packed sarcomeres (21, 22).

ES-derived cardiomyocytes express a number of cardiomyocyte-specific genes, including the transcription factors GATA4 and Nkx2.5, which play a significant role in heart formation in vertebrates (23). In addition, in this study the cardiac proteins ANP, cTnI, cTnT,
MLC-2A, MLC-2V, and α-myosin heavy chain were also found to be expressed. MLC-2A expression was also noted in the undifferentiated ES cells, but was markedly increased in the contracting EBs. This expression probably reflects some background differentiation of the ES cells on the feeder layer. The presence of both MLC-2A and MLC-2V might suggest the presence of a number of cardiomyocytic cell types within the contracting areas.

The extracellular recordings, the [Ca\textsuperscript{2+}]-transients, and the pharmacological studies clearly demonstrate that the contracting areas within the EBs displayed physiological properties consistent with cardiomyocytic tissue and significantly differed from noncardiac (skeletal or smooth) muscle. All components of normal cardiac excitation-contraction coupling were demonstrated within this tissue, namely electrical activation, increase in [Ca\textsuperscript{2+}], and the resulting contraction.

Little is known about calcium handling in the normal developing human heart. [Ca\textsuperscript{2+}]-transients in adult human atrial tissue, studied using fura-2 (24), were similar to the ones recorded in the present study with respect to total duration of the [Ca\textsuperscript{2+}]-transient and to time of half-peak calcium relaxation. However, the time to peak transient in the EBs (130 ± 27 milliseconds) was longer than the one obtained in human atrial myocytes (52.5 ± 3.1 milliseconds). This difference may have been the result of a number of causes. In the murine ES model, the contracting areas within EBs were shown to be a mixture of atrial, ventricular, and sinus nodal cells (25). Given that different cardiomyocyte types display different calcium characteristics (26), it is possible that the [Ca\textsuperscript{2+}]-transients measured in whole beating EBs, in the current study, represent a superposition of a mixed population of myocytes with fast and slow cell characteristics. Alternatively, the lower rate in [Ca\textsuperscript{2+}], rise may have been due to lower efficiency and immaturity of the calcium machinery in early developing cardiac cells.

The extracellular recordings demonstrated a sharp and a slow component most probably consistent with a relatively long action potential duration characteristic of cardiomyocytes. Fetal and neonatal human skeletal muscle cells in culture, on the other hand, display a much shorter action potential, with mean action potential duration at 50% of depolarization (APD\textsubscript{50}) of only 7.5 milliseconds (27). The positive and negative chronotropic responses to isoproterenol and carbamylcholine demonstrated the presence of functional adrenergic and cholinergic receptors, respectively, in pacemaker cells. A major pathway of the β-adrenoreceptor-dependent chronotropic response is the activation of adenylate cyclase and the consequent rise in cytosolic cAMP and stimulation of protein kinase. The positive chronotropic effect exerted by forskolin, a direct activator of adenylate cyclase, and by IBMX, a phosphodiesterase inhibitor, suggests that this signaling pathway is already present early in human cardiomyocytic differentiation.

Differences between the murine and human models. Several differences distinguish human and mouse ES cells. Human ES cells have a slightly different morphology and form flatter colonies. The stage-specific embryonic antigen-3 and antigen-4, as well as TRA-1-60 and TRA-1-81, have been shown to be expressed by human but not by mouse ES cells (10). In contrast to the mouse, human ES cells differentiate when cultured in the absence of MEF feeder layer, even in the presence of leukemia inhibitory factor.

The differences between the human and mouse cell lines are not limited to the stem cells. In the normal embryo, heart formation begins with the initiation of differentiation by myocardial and endocardial precursors and leads up to the formation of the cardiac valves. These events cover the first 12 days in the life of a mouse embryo and the first 35 days in the life of a human embryo (23). It is not surprising, therefore, that differentiation of human ES cells into cardiomyocytes proceeds at a slower rate than in mouse ES cells. In the mouse model, ES cells are cultivated in hanging drops for 2 days and are further cultivated as EBs in suspension for 5 days. Spontaneously contracting areas appear 1 day after plating, and, within 2–10 days, 80–90% of EBs reveal pulsating areas (28). In the human ES cell differentiation system described here, cells were grown in suspension for 10 days, and spontaneous contractions did not commence before day 4 after plating, with the median value being 11 days. Furthermore, only 8.1% of EBs revealed pulsating areas. These variations may represent differences between the species, differences between the cell lines, or some yet undetermined factor required in the in vitro differentiation of human ES cells. Several factors that may be optimized in the future to increase cardiomyocytic yield include different serum content, length of suspension period, the use of growth factors, or the use of supporting stroma.

Morphologically, in vitro differentiation of human and mouse ES cells appears to follow parallel pathways. The assembly of the Z-line from periodically aligned Z-bodies and the transition from disorganized myofibrils to the more organized sarcomeric pattern described here have also been noted in the mouse model (7). In the two models, different degrees of myofibrillar assembly coexist within adjacent cardiomyocytes in the same EB and within the same cell. Nevertheless, in the human model, ultrastructural maturation proceeded much more slowly, seemed more heterogeneous, and did not reach the fully mature adult phenotype during the observation period.

Possible research and clinical applications. Establishment of a cardiomyocyte differentiating system from human ES cells may become a powerful tool for understanding cardiac development and function, as human cardiomyocytes are not accessible in adequate quantities for research, especially at this early stage of differentiation. Specifically, important insights may be gathered with regard to the mechanisms involved in cardiac lineage commitment, the process of sarcomeric organization,
action potential and ion channel development, pacemaker organization, calcium handling, and establishment of the adrenergic and cholinergic receptors, as well as the molecular signals involved in these processes.

Another attractive application of these cells is in cell replacement therapy. Adult cardiomyocytes withdraw permanently from the cell cycle during differentiation; hence, any significant loss of cardiomyocytes (as occurs, for example, during myocardial infarction) is irreversible and leads to diminished cardiac function and to the development of progressive heart failure. A potential novel approach for this situation may be the implantation of myogenic cells within the infarcted tissue (1, 2, 29, 30). Although a number of myocyte preparations have been suggested, the inherent electrophysiological, structural, and contractile properties of cardiomyocytes strongly suggest that they may be the ideal donor cell type. Because human fetal cardiomyocytes cannot be obtained in sufficient numbers for clinical purposes, the use of cardiomyocytes derived from ES cell lines may become an attractive option. Nevertheless, several obstacles must be overcome in order to achieve this goal, including the generation of enriched and relatively pure cardiomyocyte cultures and the establishment of different strategies to counter immune rejection.

In summary, this study described the generation of a reproducible cardiomyocyte differentiation system from human ES cells. The generated myocytes were shown to display functional and structural properties consistent with early-stage cardiomyocytes. The establishment of this unique system may have an important impact on the understanding of human cardiac development and function, and may provide a powerful research and clinical tool in several fields such as pharmacological and toxicological testing, functional genomics, early cardiomyogenesis, cell therapy, and tissue engineering.
