SCID, a syndrome characterized by the absence of T cells and adaptive immunity, can result from mutations in multiple genes that encode components of the immune system. Three such components are cytokine receptor chains or signaling molecules, five are needed for antigen receptor development, one is adenosine deaminase—a purine salvage pathway enzyme, and the last is a phosphatase, CD45. In this issue of the JCI, a report describes how complete deficiency of the CD3ε chain of the T cell antigen receptor/CD3 complex causes human SCID (see the related article beginning on page 1512).

Human SCID was first reported by Glanzmann and Riniker in 1950 (1). Swiss infants with the condition were profoundly lymphopenic and died of infection before their first or second birthdays. In the ensuing years, differences were noted in inheritance patterns for SCID. This indicated that there was more than one cause for this fatal syndrome characterized by an absence of T cells and all adaptive immunity. In many families there was an X-linked recessive mode of inheritance while in others an autosomal recessive mode of inheritance was observed. The first discovered molecular cause of human SCID, adenosine deaminase deficiency, was reported in 1972 (2). However, it was not until 21 years later, in 1993, that a second fundamental cause of the condition was found, i.e., the molecular basis of X-linked human SCID (3, 4). Over the past 11 years, differences were noted in inheritance patterns for SCID. This emphasized the need to study affected tissues when seeking evidence of gene mosaicism. Patterened epidermal and dermal mosaic disorders (such as morphea and focal dermal hypoplasia) provide an ideal focus for future investigations that will elucidate the mechanisms of embryologic development of both ectodermal and mesodermal tissues.

The product of one gene (adenosine deaminase) is necessary for detoxification of metabolic products of the purine salvage pathway that cause lymphocytes to apoptosis; and the final gene encodes CD45, a phosphatase that serves as a critical regulator of signaling thresholds in immune cells (Table 1) (12). The most common form of human SCID is the X-linked type, caused by mutations in the gene encoding the common \( \gamma \) chain for multiple cytokine receptors; the second most common cause is adenosine deaminase deficiency (ADA def.), and the third most common cause is IL-7R\( \alpha \)-chain deficiency. In 25 cases the molecular defect remains unknown (those in the groups labeled autosomal recessive and unknown). No cases of CD45 deficiency have been seen at this institution. Def., deficiency.

Figure 1
Relative frequencies of the various molecular defects found in 174 consecutive cases of human SCID evaluated at Duke University Medical Center over the past 3 decades. The most common type is X-linked SCID, due to mutations in the gene encoding the common \( \gamma \) chain for multiple cytokine receptors; the second most common cause is adenosine deaminase deficiency (ADA def.), and the third most common cause is IL-7R\( \alpha \)-chain deficiency. In 25 cases the molecular defect remains unknown (those in the groups labeled autosomal recessive and unknown). No cases of CD45 deficiency have been seen at this institution. Def., deficiency.

Figure 2
Schematic of the T cell receptor/CD3 (TCR/CD3) complex on the surface of a normal CD4-CD8- double-negative thymocyte. All but one of the normal chains of the CD3 complex, including the \( \beta \) chain, are present, but instead of the CD3\( \alpha \) chain, the pre-T cell receptor \( \alpha \) gene is expressed at this stage. It is postulated, based on the CD3\( \varepsilon \) murine knockout studies, that the block in T cell development caused by mutations in CD3\( \varepsilon \) occurs at or just after this stage. In their study in this issue, de Saint Basile and colleagues (13) report histologic data which suggests that, in the case of mutations in the CD3\( \delta \) gene, the block in T cell maturation occurs at the next stage, i.e., at the intermediate single-positive stage.
A newly discovered cause of human SCID

The tenth known cause of human SCID is reported in this issue of the JCI by de Saint Basile et al. (13). The authors identified mutations in the gene encoding the \( \delta \) component of the T cell receptor/CD3 complex (Figure 2). Building on the discovery of Dadi et al. (11), that mutations in a gene encoding the \( \delta \) chain of the CD3 complex cause human SCID, de Saint Basile and coworkers used segregation analysis of polymorphic markers for chromosome 11q23 – the location of the CD3 locus – to study 3 families with fetuses or infants who had SCID of unknown molecular type (13). All of the fetuses or infants were characterized by the T-B-NK lymphocyte phenotype, i.e., they had no T cells but did have phenotypically normal B cells and NK cells, the same phenotype observed in the SCID infants described by Dadi et al. (11). There was a homozygous haplotype segregation of polymorphic markers for 11q23 in all 3 families studied by de Saint Basile et al. However, mutations in the gene encoding the CD3\( \delta \) chain were found in only 2 of the families. The investigators then searched for mutations in other components of the CD3 complex and found a homozygous mutation in the gene encoding CD3\( \varepsilon \) that created a premature stop codon near the start of the extracellular domain, resulting in the absence of CD3 expression in those individuals affected in the 3rd family. In 1993, members of this research group reported a child with low, but detectable, expression levels of CD3\( \varepsilon \) on circulating T cells and identified a splice site mutation on one allele that did not totally abrogate the normal intron 7 splicing (14). That child did not have impaired T cell development and had only a mild immunodeficiency (14). In the present report (13), the authors show that an absence of CD3\( \varepsilon \) completely blocks T cell development. In the CD3\( \varepsilon \) knockout mouse, this block appears to occur at the pre-T cell receptor \( \alpha \), double-negative stage. Dadi et al. (11) had concluded, based on studies of thymic material from their patients, that an absence of CD3\( \delta \) also causes a block in T cell development at the pre-T cell receptor \( \alpha \), double-negative stage of intrathymic development.

In the present report, de Saint Basile et al. (13) confirm that an absence of CD3\( \delta \) completely abrogates T cell development but conclude that the block is slightly later – at the intermediate single-positive stage, just before the double-positive (i.e., CD4+CD8\(^{+}\)) stage. Thus both CD3\( \delta \) and CD3\( \varepsilon \) appear to be essential for intrathymic development of T cells (Figure 2) whereas CD3\( \gamma \) deficiency does not (15). We have also found mutations in these two genes in our human SCID population (J.L. Roberts et al., unpublished results; Figure 1).

Importance

SCID is a pediatric emergency. If the diagnosis is made at birth or shortly thereafter, definitive therapy in the form of HLA-identical or haploidentical allogeneic bone marrow stem cell transplantation can result in a survival rate as high as 97%, regardless of the molecular type of SCID (5). However, if the diagnosis is made later, serious infections develop for which antibiotics are poorly effective or nonexistent, and the survival rate is significantly less. Allogeneic stem cell transplantation is not a perfect therapy, however, as many recipients experience incomplete B cell and/or NK cell immune reconstitution. The hope is that gene therapy could effect more complete immune reconstitution, and there has already been remarkable success in achieving this in a few patients (16–18). However, gene therapy cannot be performed unless the abnormal gene for a specific patient is known. Knowledge of the specific molecular defect is also essential for genetic counseling and prenatal diagnosis. Of the 174 SCID infants evaluated at the Duke University Medical Center over the past 3 decades, there are still 25 infants for whom the molecular basis of their disease is unknown (Figure 1). It is possible that other genes yet to be discovered can result in human SCID when mutated. Thus knowing all of the normal genes that result in human SCID is an important ongoing goal for all who work in this area.
