Neurotoxicity from accumulation of misfolded/mutant proteins is thought to drive pathogenesis in neurodegenerative diseases. Since decreasing levels of proteins responsible for such accumulations is likely to ameliorate disease, a therapeutic strategy has been developed to downregulate almost any gene in the CNS. Modified antisense oligonucleotides, continuously infused intraventricularly, have been demonstrated to distribute widely throughout the CNS of rodents and primates, including the regions affected in the major neurodegenerative diseases. Using this route of administration, we found that antisense oligonucleotides to superoxide dismutase 1 (SOD1), one of the most abundant brain proteins, reduced both SOD1 protein and mRNA levels throughout the brain and spinal cord. Treatment initiated near onset significantly slowed disease progression in a model of amyotrophic lateral sclerosis (ALS) caused by a mutation in SOD1. This suggests that direct delivery of antisense oligonucleotides could be an effective, dosage-regulatable means of treating neurodegenerative diseases, including ALS, where appropriate target proteins are known.

Introduction

Neurodegenerative diseases such as Alzheimer disease, Parkinson disease, Huntington disease, and amyotrophic lateral sclerosis (ALS) have been linked to aggregated, toxic proteins (1). One therapeutic approach for such diseases is to reduce the levels of the accumulated proteins. Accomplishing this task is a challenge due in part to the limited permeability of the blood-brain barrier. This difficulty can be surmounted by directly injecting a viral vector encoding a transcription-based siRNA into a specific brain (2–4) or spinal cord (5) region or by exploiting retrograde delivery to spinal motor neurons after viral injection into muscle (3, 5–8). Current viral vectors, however, provide no mechanism for altering dosage or discontinuance of therapy and face significant challenges for reaching widespread areas of the CNS.

Short, synthetic oligonucleotides (15–25 nucleotides) bind by Watson-Crick hybridization to target mRNA in a sequence-specific manner. The mRNA in such a heteroduplex is a substrate for catalytic, intranuclear degradation by endogenous RNase H (9). The main hurdle for using antisense oligonucleotides in the brain and spinal cord is effective delivery to these tissues. Cerebral ventricles are cavities within the brain that contain cerebrospinal fluid (CSF) that is produced by the choroid plexus (10). Once produced, CSF circulates from the ventricles to all regions of the CNS, yielding complete replacement approximately 3 times a day (10). Exploiting this and the enhanced tolerability and potency of second-generations of oligonucleotides (9) and the fact that drug administration by direct pumping into the CSF is routinely done in humans (11, 12), we describe herein a effective, dosage-regulatable method of gene therapy capable of reducing expression of genes within the CNS regions involved in the major human neurodegenerative diseases.

Results

A 20-mer oligonucleotide (SOD146192) targeting superoxide dismutase 1 (SOD1) with phosphorothioate modifications throughout and 2′-O-(2-methoxy)ethyl substitutions on the sugars of the first and last 5 nucleotides to increase biological half-lives and binding affinity (refs. 13–15; see Methods) was continuously pumped into the right lateral ventricle of a normal rat via a catheter surgically implanted through the skull and connected to an osmotic pump imbedded subcutaneously. Brain and spinal cord tissues were collected after 14 days of infusion, and concentrations of accumulated oligonucleotide were directly measured (Figure 1A). Significant oligonucleotide concentrations (3.5–7 μM) were achieved not only in the brain and brainstem but also in all levels of the spinal cord after delivery to rats (Figure 1A). Similar concentrations were achieved after infusion into a nonhuman primate (Figure 1B), including in the lumbar spinal cord more than 25 cm from the site of infusion. These micromolar tissue concentrations are on par with the 1–6 micromolar concentrations of commonly used CNS active drugs such as antiseizure medications (16).

Similar infusion performed for 14 days with a tracking oligonucleotide (Isis13920) that shares the same chemical structure and is recognized by the monoclonal antibody 2EI (17) confirmed delivery to all levels of the spinal cord, with prominent uptake in the ventral horn (Figure 1, C–E) as well as robust cellular uptake by lumbar motor neurons and the non-neuronal cells surrounding them, especially in primates (Figure 1, F–I). In addition, uptake of oligonucleotide in primates was demonstrated in the brain parenchyma relevant to neurodegenerative diseases, including the hippocampus, substantia nigra, pons, and cerebellum (Figure 1, J–M). Thus antisense oligo-
nucleotides not only distribute widely throughout the CNS of both rats and monkeys, but also penetrate deeply within tissues.

SOD1 accumulates to approximately 1% of total brain protein (18), and mutations in the gene encoding it are responsible for 20% of familial ALS (19), a progressive neurodegenerative disease caused by preferential loss of neurons in the upper and lower motor pathways and for which current treatments are marginally beneficial (18). Infusion of a scrambled oligonucleotide with identical composition and chemical modifications but altered sequence produced no effect demonstrated by identifying antisense oligonucleotides that required complementarity of the oligonucleotide to its target mRNA, producing a dose-dependent reduction to approximately 40% the normal level in cervical spinal cord (data not shown). An optimal dose of 100 μg/d was determined, above which no further reduction was seen. Infusion at this dosage for 28 days produced reduction in SOD1 mRNA levels to 25–40% of normal within the brain and at all spinal cord levels relative to infusion of saline only (Figure 3A). No diminution of accumulation of SOD1 protein was seen after only 14 days of infusion, consistent with the long protein half-life of this very stably folded polypeptide (22). Infusion for 28 days, however, was accompanied by a 50% reduction in SOD1 protein levels in right frontal cortex and lumbar and cervical spinal cord (Figure 3, B–D). In each CNS compartment examined, suppression of SOD1 mRNA was biased toward specific brain regions: SOD1 antisense oligonucleotide infusion (20, 21). Continuous infusion of the SOD1 antisense oligonucleotide (SOD1-146192), found to be most effective in cell culture, for 14 days into the right ventricle of normal rats effectively suppressed endogenous rat SOD1 mRNA, producing a dose-dependent reduction to approximately 40% the normal level in cervical spinal cord (data not shown).

Continuous infusion of the SOD1 antisense oligonucleotide (SOD1-146192), found to be most effective in cell culture, for 14 days into the right ventricle of normal rats effectively suppressed endogenous rat SOD1 mRNA, producing a dose-dependent reduction to approximately 40% the normal level in cervical spinal cord (data not shown). An optimal dose of 100 μg/d was determined, above which no further reduction was seen. Infusion at this dosage for 28 days produced reduction in SOD1 mRNA levels to 25–40% of normal within the brain and at all spinal cord levels relative to infusion of saline only (Figure 3A). No diminution of accumulated SOD1 protein was seen after only 14 days of infusion, consistent with the long protein half-life of this very stably folded polypeptide (22). Infusion for 28 days, however, was accompanied by a 50% reduction in SOD1 protein levels in right frontal cortex and lumbar and cervical spinal cord (Figure 3, B–D). In each CNS compartment examined, suppression of SOD1 required complementarity of the oligonucleotide to SOD1 mRNA, as infusion of a scrambled oligonucleotide with identical composition and chemical modifications but altered sequence produced no change in either SOD1 mRNA or protein (Figure 3, A–D).

The feasibility of this gene downregulation strategy was further demonstrated by identifying antisense oligonucleotides that direct degradation of mRNAs encoding target proteins involved in Alzheimer disease, including presenilin 1, part of the γ-secretase complex that processes amyloid precursor protein to produce...
Antisense oligonucleotides completely complementary to human SOD1 mRNA were synthesized, and the most effective at targeting human SOD1 mRNA degradation was determined by transfection into a human cell line. The best of these was tested for efficacy in a rat model that develops ALS-like progressive motor neuron disease from expression of a multicycloprenogene encoding human ALS-linked mutant SOD1(G93A) to approximately 5% of total brain protein (27), that is, between 5 and 10 times the already abundant level found in endogenous wild-type rat SOD1. SODr/h33361, the lead human oligonucleotide, suppressed mRNA and protein in vivo both after intraperitoneal administration (Figure 4A) and following intraventricular infusion for 1 month into SOD1(G93A) transgenic rats (Figure 4, B–D). Directed degradation to approximately 20% the initial level of human SOD1 mRNA in the context of human RNA binding and processing components was demonstrated after introduction (by transfection) of oligonucleotide SODr/h33361 into fibroblasts from a symptomatic ALS patient carrying a mutant SOD1(A4V) gene (Figure 5).

Oligonucleotide treatment to lower mutant human SOD1(G93A) accumulation in the rat ALS model was initiated at 65 days of age (~30 days prior to the age of disease onset; ref. 28) and rats were monitored for changes in weight, clinical signs of weakness, and survival. Infusion of saline only, SODr/h33361, and a scrambled oligonucleotide control produced indistinguishable disease onsets of 95 ± 8 (n = 11), 95 ± 10 (n = 12), and 97 ± 13 days (n = 8), respectively (Figure 6A). Early disease, as measured by loss of 10% of peak body weight, was similarly unaffected by treatment (saline, 111 ± 6 days; SODr/h33361, 112 ± 7 days; scrambled oligonucleotide, 112 ± 13 days; Figure 6B). Remarkably, despite human SOD1(G93A) accumulation to greater than 5% of total brain protein and the absence of slowing of early disease, infusion of SODr/h33361 slowed disease progression, extending survival to 132 ± 7 days compared with 122 ± 8 days in saline-infused rats (Figure 6C), a 37% extension of the typical survival duration.
27-day disease duration after onset. Survival after scrambled oligonucleotide infusion (121 ± 9 days) was no different than saline.

Discussion

The strategy reported here provides an effective method for gene downregulation that may be applicable to multiple neurodegenerative diseases and incorporates 2 central advantages over current viral gene therapy approaches (29–31). Antisense oligonucleotide infusion can be regulated or stopped should there be any unforeseen side effects, a key consideration for human application. Well-established and sophisticated pump technology allows dosing to be adjusted noninvasively by remote signaling (11, 12). Surgical implantation and pump replenishing is routine, allowing infusion indefinitely (11, 12). Safety of locally and systemically administered oligonucleotides in patients is well established, with over 500 human subjects already exposed to oligonucleotides with the chemical backbone modifications used here (32). While siRNA to direct selective mRNA degradation using the multicomponent RNA-induced silencing complex (33) is an alternative to DNA oligonucleotides, the more rapid turnover of siRNAs (even when modified to enhance stability) requires infusion of substantially higher dosages to target even relatively rare mRNAs in the CNS (34). Moreover, since siRNAs obligatorily bind to and can saturate components required for endogenous small RNA pathways, this can produce serious “off-target” consequences, including death, from dysregulation of endogenous small RNAs (35).

Figure 3

Antisense oligonucleotides reduce rat SOD1 in v/vv. (A–D) Antisense SOD1 oligonucleotides SOD$_{r146192}^{[146192]}$ or SOD$_{scrambled}^{[scrambled]}$ were infused for 28 days into the right lateral ventricle of normal rats at 100 μg/d. (A) Endogenous SOD1 mRNA levels from brain and spinal cord regions were measured by quantitative real-time RT-PCR. Mean ± SD are shown (n = 6). (B) SOD1 and α-tubulin protein levels were analyzed by immunoblotting following infusion. The Coomassie-stained gel at top demonstrates equal loading. (C and D) Protein levels for tubulin and SOD1 were quantified for right cortex, cervical cord, and lumbar cord after infusion as in B. Mean ± SD are shown (n = 6). (E) Antisense oligonucleotides against presenilin 1 or GSK-3β were infused for 2 weeks into the right lateral ventricle of nontransgenic mice, and mRNA levels were measured by quantitative RT-PCR in the right frontal/temporal cortex (n = 6).

Figure 4

Antisense oligonucleotides complementary to human SOD1 mRNA decrease SOD1 protein levels in SOD1$^{G93A}$ rat liver and spinal cord. (A) An oligonucleotide active against human SOD1 mRNA as well as a rat mRNA–specific oligonucleotide (SOD$_{146192}^{[146192]}$) was injected intraperitoneally 3 times per week (37.5 mg/kg at a concentration of 3 M) into adult rats expressing a low copy number human SOD1$^{G93A}$ transgene (line L28L; ref. 27). After 3 weeks, liver extracts were prepared and analyzed by immunoblotting using an antibody that recognizes rat and human SOD1 with equal affinity (18). (B–D) Antisense oligonucleotides complementary to human SOD1 mRNA were infused into the right lateral ventricle of 65-day-old SOD1$^{G93A}$ rats at 100 μg/d for 28 days. (B) RNA was prepared from tissue extracts, and SOD1 RNA levels were measured by real-time RT-PCR. (C and D) Protein levels for SOD1 and α-tubulin were analyzed in parallel extracts by immunoblotting with an antibody recognizing human and rat SOD1 with equal affinity (C) and were quantified for cervical cord (D). $^*P < 0.05$ versus SOD$_{scrambled}^{[scrambled]}$; Student’s t test. Mean ± SD are shown (n = 4 [SOD$_{scrambled}^{[scrambled]}$]; 8 [SOD$_{r/h333611}^{[r/h333611]}$]).
An additional benefit of the antisense oligonucleotide infusion method is widespread distribution and uptake in some or all of the non-neuronal cells within each CNS domain. For SOD1 mutant-mediated ALS, toxicity to motor neurons is non-cell autonomous, with wild-type non-neuronal cells capable of delaying or eliminating degeneration and death of mutant-expressing motor neurons, and wild-type neurons acquiring damage from mutant-expressing neighbors (36). The slowing of disease after onset with oligonucleotide infusion contrasts with earlier gene therapy approaches using peripheral injection of an siRNA-encoding virus coupled with its delivery to motor neurons through retrograde transport (6, 7). These strategies failed to slow disease progression after onset, and in one instance disease progression was significantly accelerated (by 30%; ref. 7) despite treatment initiated in juvenile (7-day-old) mice. These findings may be explained by failure to suppress mutant action in the non-neuronal cells.

Since diminished dismutase activity (37) or even complete absence of SOD1 (38) does not produce overt disease, compromise lifespan, or affect SOD1 mutant–mediated disease in mice (39), our results support infusion of antisense oligonucleotides as a treatment of familial ALS, especially for patients with the SOD1 mutation, which accounts for approximately 50% of SOD1-mediated ALS in the United States and has an unusually rapid disease course after onset (40). The significantly lower normal levels of potential disease targets, including amyloid precursor protein (0.05%; refs. 41, 42), presenilin 1 (0.0003%; ref. 23), tau (0.01–0.1% of total brain protein; ref. 43), and α-synuclein (0.5%; ref. 44), makes this approach even more attractive in these other diseases. This is especially so for targets that are nonessential genes whose absence does not compromise lifespan in mice, including amyloid precursor protein (45), the BACE protease, whose action is required to generate the Aβ peptide in Alzheimer disease (46), and tau (47). Even for gene products for which loss of function has a phenotype (e.g., Huntington; refs. 48, 49, and presenilin 1; ref. 50), and which provide essential roles during early embryogenesis (48, 49), expression may not be necessary in adult neurons or their non-neuronal neighbors. Widespread oligonucleotide delivery in primates at levels sufficient to suppress even a very abundant mRNA (Figure 1) indicates that oligonucleotide therapy that effectively decreases the intended target can reach the relevant brain regions in human diseases including ALS, Alzheimer disease, frontal temporal dementia, Parkinson disease, and Huntington disease. If the formal safety studies underway in animals and the planned Phase I trial in human familial ALS patients demonstrate adequate safety (admittedly a substantial hurdle for any novel therapy), there are indeed many potential targets with a real possible impact on neurodegeneration.

**Methods**

Oligonucleotide preparation and synthesis and screening. For each target mRNA, 78 oligonucleotides corresponding to regions within the coding regions and 5′ and 3′ untranslated regions were synthesized and purified as described previously (51). Oligonucleotides were phosphorothioate-modified chimeric oligonucleotides composed of five 2′-O-(2-methoxy)ethyl modifications on both the 5′ and 3′ ends and 10 oligodeoxynucleotides in the center to support RNase H activity (13). Initial in vitro screening was performed by transfection of oligonucleotide (at 150 nM with 3.75 mg/ml Lipofectamine; Invitrogen) into a rat aortic cell line (A10 cells) for rat oligonucleotides and into a human lung cancer cell line (A549 cells) for human oligonucleotides as described (13). Twenty-four hours after transfection, cells were harvested, and mRNA levels were measured by quantitative RT-PCR as described below. Oligonucleotide sequences were as follows, with underlined portions corresponding to 2′-O-(2-methoxy)ethyl modifications: SOD1 (5′-GTTCGCCCTTCAGACAGCACA-3′; SOD1r/h146145); SOD1 (5′-CGGTCGCCCTTCAGACAGCACA-3′; SOD1r/h333611); SOD1 (5′-CCCTCCCTGCAGGTCCAGGACAGCACA-3′; SOD1r/h146142) (SOD1promisor control oligonucleotide), 5′-TCCTCCCTGAAAGTGCTTCCTCGCA-3′, SOD1r/h333612; 5′-CTACAGTTTAGAGAGAGAGACAGCACAAG-3′, GSK-3β, 5′-3CTCATGATGCTGGAGCTTCCTGC-3′, and presenilin 1, 5′-AGCCATGGGTCAAGAGAGAGAGAGAGAGAGAGACAGCACA-3′. We
selected SOD1G93A as a control oligonucleotide because it shares identical chemistry and length to the SOD1-targeted oligonucleotides, is not predicted to hybridize to any known human or rat genes, and was previously shown not to have detectable effects in tissue culture or in mouse models (52, 53).

Quantitative RT-PCR. mRNA levels were measured by a quantitative real-time RT-PCR method (54). Total RNA was isolated using an RNeasy Mini prep kit (QIAGEN) according to the manufacturer’s protocol. We combined 5–10 ng total RNA with 100 nM of each of the gene-specific dual-labeled probes and forward and reverse primers in a buffered solution consisting of 1× TaqMan Buffer A (Applied Biosystems), 5.5 mM MgCl₂, 200 μM concentrations of each dNTP (Amersham Biosciences), 2 U RNase inhibitor, 0.625 U AmpliTaq Gold, and 6.25 U murine leukemia virus reverse transcriptase. Except for dNTP solutions, all reagents above were obtained from Applied Biosystems. Quantitative RT-PCR reactions were conducted and analyzed on an ABI Prism 7700 Sequence Detector (Applied Biosystems). Glyceraldehyde 3-phosphate dehydrogenase mRNA levels were used as an internal reference for normalization among samples. Primer probe set sequences for SOD1 were as follows: forward, 5′-TGCT-GAAGGGCCAGCGG-3′; reverse, 5′-GGTACCGCCTGCTTGCT-3′; probe, 5′-CCGGTGACAGGGGCACTTACCT-3′.

Quantitation of oligonucleotide concentrations. In order to determine the tissue concentration of oligonucleotides, approximately 100 mg tissue were homogenized (Bio Savant, Bio 101 Inc.), phenol-chloroform was extracted, and solid phase was extracted using a phenyl-bonded SPE column (International Biotechnologies) (55). Extracted samples were analyzed by capillary gel electrophoresis (CGE) using a Beckman P/ACE MDQ Model 5010 Capillary Electrophoresis instrument (Beckman Coulter) with UV detection at 260 nm (56). Quantitation of oligonucleotide was performed using standard curves of electropherogram peak area ratios (drug/internal standard) versus known concentrations over the anticipated concentration range or by the extinction coefficient method (56). Calibration curve and quality control samples were run with each unknown sample analysis. No oligonucleotide was detected by CGE in the saline-treated control samples. The limit of quantitation for the assay was estimated to be 0.35 μg/g (0.05 μM) oligonucleotide in tissue.

Surgical placement of osmotic pumps and harvesting tissues for analysis. Sprague-Dawley rats (65–75 days old) were anesthetized with intramuscular administration of ketamine, acepromazine, and xylazine. Subsequently, after sterilizing the surgical site with betadine, a midline incision was made over the skull, and a subcutaneous pocket was created over the back. An osmotic pump (ALZET Osmotic Pumps) that had been filled with oligonucleotide and incubated overnight in saline at 37°C was implanted in the pocket. To deliver 100 μg/d, oligonucleotides were diluted to 16.7 mg/ml in preservative-free, sterile 0.9% sodium chloride. The animal was placed in a stereotactic frame at which time a small burr hole was made through the skull immediately above the right lateral ventricle. A cannula, connected to the pump via a plastic catheter, was then placed in the ventricle, and the incision was manually closed with sutures. Depending on the experiment, oligonucleotide was infused for either 14 or 28 days, after which animals were anesthetized with isoflurane and sacrificed. Brain and spinal cord were rapidly removed (with approximately 100 mg tissue) and incubated overnight in saline at 37°C was implanted in the pocket. To deliver 100 μg/d, oligonucleotides were diluted to 16.7 mg/ml in preservative-free, sterile 0.9% sodium chloride. The animal was placed in a stereotactic frame at which time a small burr hole was made through the skull immediately above the right lateral ventricle. A cannula, connected to the pump via a plastic catheter, was then placed in the ventricle, and the incision was manually closed with sutures. Depending on the experiment, oligonucleotide was infused for either 14 or 28 days, after which animals were anesthetized with isoflurane and sacrificed. Brain and spinal cord were rapidly removed (with approximately 100 mg tissue). RNA was immediately processed as described above. Tissues for subsequent analysis were placed in liquid nitrogen and stored at −80°C. The SOD1G93A rat line L26L (27) (lower expressing) was used for initial evaluation of mRNA and protein levels. All animal protocols were approved by the UCSD Institutional Animal Care and Use Committee and met ethical standards for animal experimentation.

Assessment of onset and survival. For survival experiments, death was defined by paralysis so severe that the animal was unable to right itself within 30 seconds when placed on its side, a common endpoint that is objective and minimizes distress for the experimental animals. Animals were weighed weekly. Onset was defined retrospectively by analyzing the first sign of weight loss. We defined 10% weight loss as the point when the animals lost 10% of their peak body weight. Nontransgenic control animals did not lose weight. For survival experiments, the SOD1G93A L26H (higher expressing) rat line was used.

Immunoblotting. Tissues for immunoblotting were thawed on ice and then homogenized in lysis buffer (1% Triton X-100, 50 mM Tris-HCl, pH 7.5; 150 mM NaCl; and protease inhibitor mixture containing 1 μg/ml aprotonin, 1 μg/ml leupeptin, and 1 mM PMSF). After centrifugation, the clarified supernatant was used for subsequent analysis. Lysates were resolved by 12% SDS/PAGE and transferred to nitrocellulose membranes (Schleicher & Schuell). Membranes were incubated with SOD1 antibody (18) or α-tubulin antibody (Sigma-Aldrich) diluted 1:2,000 or 1:3,000, respectively, in 5% nonfat skim milk/0.1% Tween 20 in PBS, and were then incubated with Horseradish Peroxidase–conjugated Anti-Rabbit or Anti-Mouse IgG (Amersham Biosciences) and visualized with ECL (Amersham Biosciences). Immunoblots were quantified using Image J (a public domain Java image processing program inspired by NIH Image; http://rsb.info.nih.gov/ij/). Anti-GFAP antibodies were purchased from Abcam.

Infusion of oligonucleotides into Rhesus monkeys. Under anesthesia, catheters were surgically implanted in the left lateral ventricles of 5 Rhesus monkeys approximately 3 years of age, after which the animals recovered for 5 days. Catheters terminated in a subcutaneous titanium access port that was connected to an external pump housed within a jacket on the animal. Isis® (20) (tracking oligonucleotide) was continuously infused into the left lateral ventricle of 2 animals at a concentration of 1.7 mg/ml in saline, for a total dose of 1 mg/d. Control animals (n = 3) were infused with saline at a similar rate. No adverse behavioral effects were noted. After 14 days, animals were euthanized, and tissues were collected.

Statistics. Data were analyzed using 2-tailed Student’s t test. P values less than 0.05 were considered significant.
