Focal segmental glomerulosclerosis (FSGS) is the most common primary glomerular diagnosis resulting in end-stage renal disease. Defects in several podocyte proteins have been implicated in the etiology of FSGS, including podocin, α-actinin-4, CD2-associated protein (CD2AP), and TRPC6. Despite our growing understanding of genes involved in the pathogenesis of focal segmental sclerosis, the vast majority of patients with this disease, even those with a familial linkage, lack a clear genetic diagnosis. Here, we tested whether combinations of genetic heterozygosity (bigenic heterozygosity) that alone do not result in clinical kidney disease could function together to enhance susceptibility to glomerular damage and FSGS. Combinations of Cd2ap heterozygosity and heterozygosity of either synaptopodin (Synpo) or Fyn proto-oncogene (Fyn) but not kin of IRRE like 1 (Neph1) resulted in spontaneous proteinuria and in FSGS-like glomerular damage. These genetic interactions were also reflected at a functional level, as we found that CD2AP associates with Fyn and Synpo but not with Neph1. This demonstrates that bigenic heterozygosity can lead to FSGS and suggests that combined mutations in 2 or multiple podocyte genes may be a common etiology for glomerular disease.

Introduction
Focal segmental glomerulosclerosis (FSGS) is a major cause of end-stage renal disease and is increasing in frequency (1). The structure affected in FSGS is the kidney glomerulus, which is composed of capillaries that are involved in the filtration of blood. The diagnosis of FSGS is based on the clinical findings of proteinuria and specific histopathological changes, with areas of glomerular sclerosis and glomerular tuft collapse that are both focal and segmental. Focal refers to the finding that not all glomeruli are affected, and segmental indicates that only a portion of the affected glomerulus is sclerosed. While the etiology of most cases of FSGS is unknown, the heterogeneous nature of these histologic changes suggests that a combination of different factors is involved, including genetic and environmental influences (2, 3).

The podocyte, the visceral epithelial cell of the glomerulus, has taken center stage in research on the pathogenesis of FSGS. Genetic studies in both human and mouse reveal that the development of FSGS is initiated by podocyte dysfunction (2). In humans, mutations of the podocyte-specific gene nephrosis 2 homolog, podocin (Nphs2) (encoding podocin) (4), the more ubiquitously expressed cytoskeletal protein α-actinin-4 (5), and the ion channel protein TRPC6 (6, 7) have been shown to impair podocyte function and to cause an inherited form of FSGS. Mouse studies demonstrate that the complete absence of either podocin (8) or α-actinin-4 (9) results not in FSGS but in a severe podocyte dysfunction leading to a lethal nephrotic syndrome that occurs at or near birth. The complete absence of other gene products that are either podocyte specific, such as nephrin (10) and kin of IRRE like 1 (Neph1) (11), or more ubiquitously expressed, such as CD2-associated protein (CD2AP) (12), can also lead to severe podocyte dysfunction and congenital nephrotic syndrome.

These studies suggest that the degree of podocyte dysfunction determines whether congenital nephrotic syndrome or FSGS occurs. Severe impairment of podocyte function would lead to perinatal glomerular failure while a more modest impairment would require additional environmental factors before focal and segmental changes in glomeruli could occur (2).

In this study, we were interested to explore whether combinations of heterozygosity for different podocyte-relevant genes would increase the risk for FSGS. We therefore crossed mice heterozygous for Cd2ap with mice that are heterozygous for the signaling protein Fyn proto-oncogene (Fyn), the long isoform of the actin-bundling protein synaptopodin (Synpo), or the slt diaphragm protein Neph1. While Cd2ap-null mice develop nephrotic syndrome and end-stage renal disease early in life, the clinical phenotype of Cd2ap heterozygous animals is relatively unremarkable (13). However, bigenic heterozygosity of Cd2ap with Fyn or Synpo but not Neph1 resulted in a significantly increased incidence of proteinuria and pathological changes consistent with FSGS. This suggests that combined mutations of genes in pathways involving CD2AP, Fyn, and Synpo may account for a significant fraction of patients with FSGS.

Results
Bigenic heterozygosity of Cd2ap and Fyn leads to proteinuria. We first bred Cd2ap heterozygous mice to Fyn-deficient mice on a pure C57BL/6J background. Fyn is a Src-family tyrosine kinase that is
expressed in podocytes, where it has been shown to phosphorylate
the slit diaphragm component nephrin (14). While Yu et al. report-
ed that most Fyn−/− mice develop mild proteinuria by 6 months of
age, Verma et al. were unable to detect any significant proteinuria
in Fyn+/− mice (14, 15). Both groups found no histological abnor-
malities but did demonstrate podocyte foot process effacement.
Lastly, Fyn−/− mice do not develop proteinuria or display any light
or electron microscopic abnormalities (15).

Five mouse genotypes were generated and followed up to 12
months: Fyn+/−Cd2ap+/−, Fyn+/−Cd2ap+/+, Fyn+/−Cd2ap−/−, Fyn−/−
Cd2ap+/−, and Fyn−/−Cd2ap−/−. Because proteinuria is the earliest
and most sensitive clinical indicator of glomerular dysfunction,
proteinuria was used as the primary end-point for this study.
Mice were tested monthly for the presence of albumin in the
urine and followed to up to 12 months of age. Because some
wild-type mice develop low-grade proteinuria at advanced ages,
varying with genetic background (16–18), we used only litter-
mates for controls. Proteinuric animals were typically sacrificed
within 1 month of detection. In our colony, about 31%
of Fyn−/− mice developed proteinuria, with an average age
of onset of 8 months of age, a phenotype that is interme-
diate between those in the 2 previous studies. Consistent
with what was reported previously, Fyn+/− mice did not
develop proteinuria (14, 15).

In the presence of CD2AP haploinsufficiency, 56% of
Fyn−/− mice developed proteinuria (P < 0.01 relative to
Fyn−/− alone) while the rate of proteinuria in Fyn+/− mice
was increased to 100% (Figure 1A; P < 0.0025). In addi-
tion, CD2AP haploinsufficiency significantly accelerated
the onset of proteinuria from 8 months of age to 5
months of age (P < 0.05). Near the onset of proteinuria,
the serum blood urea nitrogen (BUN) (16.6 ± 1.3 mg/dl)
and creatinine (0.57 ± 0.03 mg/dl) levels of Fyn+/−Cd2ap+/−
and Fyn−/−Cd2ap−/− mice were similar to those of wild-type
mice (C57BL/6 background). Five mice were measured
2–3 months after onset of proteinuria, with consistently
elevated creatinine levels (0.7 ± 0.03 mg/dl) and slightly
elevated BUN levels (18.8 ± 3.1 mg/dl). Proteinuria pro-
gressed in these mice from 70 ± 12 mg/dl to 200 ± 41 mg/dl
(n = 5) over this period of time.

Light microscopic examination of Fyn+/− and Fyn−/− were
consistent with previous studies and showed no signifi-
cant or only minor histological changes, such as mesan-
gial hypercellularity in some Fyn+/− glomeruli. However, in
the presence of CD2AP haploinsufficiency, there were significant
pathological glomerular changes, some of which were consistent
with FSGS. The most common finding was glomerular hypercellu-
larity with mesangial expansion seen in many but not all glomeruli
(Figure 1B). There were occasional sclerotic glomeruli and glom-
eruli with segmental sclerosis (Figure 1B). There was a tendency
toward more significant levels of sclerosis in the Fyn+/−Cd2ap+/−
mice compared with Fyn−/−Cd2ap−/− mice. The histological changes
correlated with the degree of proteinuria.

Electron microscopic examination of Fyn+/− and Fyn−/− kidneys
demonstrated mild changes, with foot process coarsening, fusion,
and effacement consistent with previous reports. In the presence
of CD2AP haploinsufficiency, these changes were more extensive
(Figure 2). In proteinuric animals, electron-dense subepithelial
and mesangial deposits were detected (Figure 2).

Bigenic heterozygosity of Cd2ap and Synpo leads to proteinuria. We
next bred Cd2ap heterozygous mice to Synpo-deficient mice
on a pure 129 background. Synpo is an actin-bundling protein

Figure 1
CD2AP haploinsufficiency enhances proteinuria in Fyn-defi-
cient mice. (A) Mice were tested monthly for proteinuria. The
incidence of proteinuria is depicted as both percentages and
absolute numbers for the indicated mouse genotypes fol-
lowed to up to 12 months of age. The onset of proteinuria is
shown below for each genotype in months ± SEM. *Statistical
significance. (B) Sections of formalin-fixed kidney cortex from
5- to 8-month-old mice were stained with H&E and with PAS.
In Fyn−/− mice, most glomeruli were normal (top right). Repres-
entative glomeruli from Fyn+/−Cd2ap+/− mice (middle row)
or Fyn−/−Cd2ap−/− mice (bottom row) taken 2 months after the
onset of proteinuria reveal mesangial hypercellularity and
segmental sclerosis or global sclerosis in some glomeruli.

expressed specifically in podocytes and in telencephalic dendrites (19). There are 3 isoforms of Synpo (Synpo-long, Synpo-short, and Synpo-T) that are generated by alternative RNA splicing (20). Recently generated Synpo–/– mice lack the Synpo-short and Synpo-long expression but still express Synpo-T isoform in podocytes (20). While these mice exhibit neuronal defects, no spontaneous kidney phenotype was detected (20, 21).

Four genotypes were generated: Synpo+/–Cd2ap+/–, Synpo+/–Cd2ap+/–, Synpo+/–Cd2ap+/–, and Synpo+/–Cd2ap+/–. The animals were evaluated in the same manner as the Fyn/Cd2ap mice. Consistent with a previous report (20), we did not detect any proteinuria in Synpo-deficient or Synpo-heterozygous animals over the year of observation (Figure 3A). In the presence of CD2AP haploinsufficiency, however, 58% of Synpo+/– and 29% of Synpo+/– mice developed proteinuria. (P < 0.00001 and P < 0.006 respectively) (Figure 3A). The average age of onset of proteinuria was 7–8 months and was not significantly different between Synpo+/–Cd2ap+/– and Synpo+/–Cd2ap+/– mice (Figure 3A). Synpo+/–Cd2ap+/– and Synpo+/–Cd2ap+/– mice measured near the onset of proteinuria had serum BUN (17.2 ± 0.9 mg/dl) and creatinine (0.46 ± 0.02 mg/dl) levels (n = 27) that were similar to those of wild-type mice (129 background). Four mice were measured 2–3 months after onset of proteinuria, with elevated BUN (50.4 ± 16.5 mg/dl) and creatinine levels (0.7 ± 0.13 mg/dl). Proteinuria increased consistently from 90 ± 6 mg/dl to 240 ± 44 mg/dl when mice were followed for 2–3 months after onset of proteinuria (n = 6). As with the Cd2ap/Fyn mice, these data indicate a progression of disease over time with worsening severity of proteinuria, leading to an eventual decline in glomerular filtration and significant glomerulosclerotic changes.

Light microscopic examination of Synpo+/– and Synpo+/– kidneys did not reveal any obvious histological abnormalities (Figure 3B), but pathological changes were obvious in Synpo+/–Cd2ap+/– and Synpo+/–Cd2ap+/– kidneys (Figure 3B). As with the Fyn/Cd2ap mice, these changes mainly involved hypercellular glomeruli with expanded mesangium in some but not all glomeruli. In addition, there were occasional glomeruli that were either completely or segmentally sclerosed (Figure 3B).

Electron microscopic examination of the kidneys from these mice showed no obvious changes in kidneys from Synpo+/– or Synpo+/– mice. In the presence of CD2AP haploinsufficiency, however, both Synpo+/– and Synpo+/– mice demonstrated sequential changes in the foot process architecture, consisting of coarsening and effacement of foot processes (Figure 4, B and C). We noted the presence of electron-dense deposits within glomerular basement membranes and mesangium (Figure 4B). Similar deposits and IgG staining have been seen in older (> 9 month old) Cd2ap heterozygous mice, as previously shown (13). Electron microscopy and immunofluorescence staining for IgG on 6- to 9-month-old Cd2ap+/–Synpo+/– (n = 15) and Cd2ap+/–Synpo+/– mice (n = 26) (data not shown) showed positive IgG staining in 13 out of 25 proteinuric mice and 8 out of 16 nonproteinuric mice. Electron-dense deposits were seen in 8 out of 23 proteinuric mice and 4 out of 16 nonproteinuric mice. Since the presence or absence of electron-dense deposits and IgG staining does not appear to correlate very well with proteinuria, we suspect that the presence of electron-dense deposits and positive IgG staining is related to the Cd2ap heterozygous background of the mice and not to the combined heterozygosity.

CD2AP haploinsufficiency combined with Neph1 heterozygosity. Neph1 is a transmembrane receptor closely related to nephrin, expressed in podocytes, brain, and smooth muscle of liver, lung, and heart (11). In the podocyte, Neph1 localizes to the slit diaphragm and is thought to function like nephrin in maintenance of the slit diaphragm (22, 23). Neph1-deficient animals, generated by retroviral insertion, are born with congenital nephrotic syndrome and usually die in the perinatal period (11).

Neph1+/– animals were bred to Cd2ap heterozygous animals to determine whether combined heterozygosity would contribute to a glomerular phenotype. Because of the mixed backgrounds of these animals, we compared only littermates, and the results were quite decisive: Neph1+/– animals did not exhibit any obvious kidney abnormalities (data not shown). Zero of 16 Neph1+/– Cd2ap+/– mice developed proteinuria over the 12-month observation period, and none of these mice exhibited any histologic abnormalities before 9 months of age (data not shown). Since bigenic heterozygosity of Neph1 and Cd2ap did not result in pro-
teinuria, the combined heterozygous effect of Cd2ap with Fyn and Synpo appears to be specific.

Cd2ap heterozygosity does not alter blood pressure. Since CD2AP is widely expressed, including in blood vessels, myocardium, and renal collecting duct, we wanted to exclude the possibility that Cd2ap heterozygosity accelerated glomerular disease by inducing hypertension. Mean arterial pressure (MAP) was measured using intraarterial pressure catheters in 4-month-old male wild-type and Cd2ap heterozygous animals (n = 7). Blood pressure was found to be normal and similar between Cd2ap heterozygous mice (MAP = 70 mmHg) and littermate wild-type and wild-type controls (MAP = 71 mmHg).

CD2AP interacts with Fyn and Synpo, but not with Neph1. The above results showing genetic epistasis between CD2AP and Fyn and between CD2AP and Synpo suggested that these proteins may function in the same pathway. We were therefore interested to determine whether CD2AP could physically interact with either Synpo or Fyn. To test for interactions between CD2AP and Fyn, immunoprecipitates prepared from human kidney cell-line lysate (Figure 5A) or rat glomerular lysates (Figure 5A) using antibodies to Fyn (polyclonal antibody) were immunoblotted with an antiserum to CD2AP. CD2AP was easily detected in Fyn but not in control antibody immunoprecipitates. This demonstrates for what we believe is the first time that endogenous CD2AP and Fyn form a constitutive complex (Figure 5A).

To test for an interaction between Synpo and CD2AP, immunoprecipitates were prepared from podocyte cell lysates using Synpo antibodies. Immunoblotting with antibodies to CD2AP showed the presence of CD2AP in Synpo lysates (Figure 5B). The converse was also true. Immunoprecipitates prepared with CD2AP antibodies and immunoblotted with antibodies to Synpo also demonstrated an interaction (Figure 5B).

To map the interacting domains, 2 mutated forms of CD2AP were used. The structure of CD2AP is notable for 3 SH3 domains at the N terminus and multiple proline-rich sequences at the C terminus. Constructs lacking the SH3 domains or the proline-rich sequences were both tested for Synpo binding. While Synpo (Synpo-long) interacted with wild-type CD2AP and a mutated form of CD2AP lacking the proline sequences, there was no detectable interaction of Synpo (Synpo-long) with the mutated form of CD2AP lacking the SH3 domains (Figure 6A). This suggests that the SH3 domains of CD2AP mediate the interaction with Synpo-long, presumably by binding to proline-rich sequences in Synpo.

To test whether the interaction between the SH3 domains of CD2AP and Synpo is direct, far Western blot experiments were performed. FLAG-tagged Synpo-long and FLAG-tagged GFP as control were blotted on a nitrocellulose membrane and subsequently incubated with biotinylated, recombinant CD2AP protein containing all 3 SH3 domains. As shown in Figure 6B, the CD2AP SH3 domains specifically bound to Synpo-long, indicating a direct SH3 domain–mediated interaction between CD2AP and Synpo.

Recently, the existence of 3 Synpo isoforms, Synpo-long, Synpo-short, and Synpo-T, has been described (20). We therefore tested whether CD2AP interacts with all isoforms of Synpo. Figure 6C shows that CD2AP can be coimmunoprecipitated with Synpo-long, Synpo-short, and Synpo-T (Figure 6C).

Lastly, since CD2AP is known to interact with nephrin, we were interested to know whether CD2AP interacts with Nep1. Immunoprecipitates were prepared using lysates from cells coexpressing CD2AP with epitope-tagged Nep1 or epitope-tagged with an antiserum to CD2AP. CD2AP was easily detected in Fyn but not in control antibody immunoprecipitates. This demonstrates for what we believe is the first time that endogenous CD2AP and Fyn form a constitutive complex (Figure 5A).

To test for an interaction between Synpo and CD2AP, immunoprecipitates were prepared from podocyte cell lysates using Synpo antibodies. Immunoblotting with antibodies to CD2AP showed the presence of CD2AP in Synpo lysates (Figure 5B). The converse was also true. Immunoprecipitates prepared with CD2AP antibodies and immunoblotted with antibodies to Synpo also demonstrated an interaction (Figure 5B).

To map the interacting domains, 2 mutated forms of CD2AP were used. The structure of CD2AP is notable for 3 SH3 domains at the N terminus and multiple proline-rich sequences at the C terminus. Constructs lacking the SH3 domains or the proline-rich sequences were both tested for Synpo binding. While Synpo (Synpo-long) interacted with wild-type CD2AP and a mutated form of CD2AP lacking the proline sequences, there was no detectable interaction of Synpo (Synpo-long) with the mutated form of CD2AP lacking the SH3 domains (Figure 6A). This suggests that the SH3 domains of CD2AP mediate the interaction with Synpo-long, presumably by binding to proline-rich sequences in Synpo.

To test whether the interaction between the SH3 domains of CD2AP and Synpo is direct, far Western blot experiments were performed. FLAG-tagged Synpo-long and FLAG-tagged GFP as control were blotted on a nitrocellulose membrane and subsequently incubated with biotinylated, recombinant CD2AP protein containing all 3 SH3 domains. As shown in Figure 6B, the CD2AP SH3 domains specifically bound to Synpo-long, indicating a direct SH3 domain–mediated interaction between CD2AP and Synpo.

Recently, the existence of 3 Synpo isoforms, Synpo-long, Synpo-short, and Synpo-T, has been described (20). We therefore tested whether CD2AP interacts with all isoforms of Synpo. Figure 6C shows that CD2AP can be coimmunoprecipitated with Synpo-long, Synpo-short, and Synpo-T (Figure 6C).

Lastly, since CD2AP is known to interact with nephrin, we were interested to know whether CD2AP interacts with Nep1. Immunoprecipitates were prepared using lysates from cells coexpressing CD2AP with epitope-tagged Nep1 or epitope-tagged.
speculated that mutations in podocyte-relevant genes might cooperate together to cause podocyte dysfunction and, subsequently, glomerular disease. CD2AP is a scaffold protein that interacts with a variety of proteins, including slit diaphragm, signaling, and cytoskeletal proteins (24). We speculated that mutations in Cd2ap might sensitize the podocyte to mutations in a wide variety of different genes. We found that heterozygosity of Cd2ap combined with heterozygosity of Synpo or Fyn led to a significant incidence of glomerular dysfunction as evidenced by proteinuria and pathological changes consistent with FSGS.

Recent progress has helped to illuminate the important role of the podocyte in the etiology of glomerular diseases like FSGS (2, 3). Mouse knockout models demonstrate that deficiencies of either podocyte-specific genes (encoding for podocin, ref. 8; nephrin, ref. 25; and Neph1, ref. 11) or more ubiquitously expressed genes (encoding for α-actinin–4, ref. 9; CD2AP, ref. 12; and Fyn, ref. 15) can result in podocyte dysfunction leading to a severe congenital nephrotic syndrome. Genetic studies in humans suggest that less severe mutations in some of these genes may be responsible for a more variable pattern of disease that may be responsible for some cases of familial and idiopathic FSGS (26).

Podocin mutations were first described in an autosomal recessive form of FSGS that occurs with variable onset in children between 2 and 10 years of age (4). Over 40 different mutations in podocin have now been described (27). Most of the affected patients with autosomal recessive nephrin. While immunoblotting of CD2AP immunoprecipitates showed the presence of nephrin, no interaction between CD2AP and Neph1 was detected under the same conditions (Figure 6E).

Discussion
Here, we tested whether combined genetic heterozygosity might play a role in the etiology of FSGS. Given the limited number of proteins implicated in podocyte-specific functions, a simple approach was to directly test whether combined heterozygosity of podocyte-relevant genes might cooperate to cause podocyte dysfunction and, subsequently, glomerular disease. CD2AP is an interaction with a variety of proteins, including slit diaphragm, signaling, and cytoskeletal proteins (24). We speculated that mutations in Cd2ap might sensitize the podocyte to mutations in a wide variety of different genes. We found that heterozygosity of Cd2ap combined with heterozygosity of Synpo or Fyn led to a significant incidence of glomerular dysfunction as evidenced by proteinuria and pathological changes consistent with FSGS.

Recent progress has helped to illuminate the important role of the podocyte in the etiology of glomerular diseases like FSGS (2, 3). Mouse knockout models demonstrate that deficiencies of either podocyte-specific genes (encoding for podocin, ref. 8; nephrin, ref. 25; and Neph1, ref. 11) or more ubiquitously expressed genes (encoding for α-actinin–4, ref. 9; CD2AP, ref. 12; and Fyn, ref. 15) can result in podocyte dysfunction leading to a severe congenital nephrotic syndrome. Genetic studies in humans suggest that less severe mutations in some of these genes may be responsible for a more variable pattern of disease that may be responsible for some cases of familial and idiopathic FSGS (26).

Podocin mutations were first described in an autosomal recessive form of FSGS that occurs with variable onset in children between 2 and 10 years of age (4). Over 40 different mutations in podocin have now been described (27). Most of the affected patients with autosomal recessive

FSGS have homoyzogous missense mutations, suggesting that the mutation causes a weak loss of function that is only able to cause disease when mutations of both alleles are present (27). Importantly, cases of increased disease susceptibility have been reported with mutations of only one podocin allele, suggesting involvement of another genetic locus (4, 26).

Mutations in the gene encoding α-actinin–4 are linked to an autosomal dominant form of FSGS in which the clinical presentation is also widely variable (5). In these patients, the disease has a late onset (first occurring in early adulthood) and is incompletely penetrant (5). Mice that are completely deficient for α-actinin–4 develop a severe congenital nephrotic syndrome (9) while mice that are heterozygous for the dominant acting K228E allele do not display any overt disease (28). These observations strongly suggest that environmental as well as other genetic factors may play important roles in determining whether disease occurs when a single copy of the disease-causing allele is present.

Here, we focused on bicoligic heterozygosity of Cd2ap. We previously showed that mice that are heterozygous for Cd2ap develop pathological changes after 9 months of age but not proteinuria (13). Cd2ap heterozygous mice, however, have an increased sensitivity to nephrotoxic injury (13). Given the mild phenotype of Cd2ap heterozygous mice, we speculated that combined heterozygous mutations in Cd2ap and other associated proteins might increase susceptibility to podocyte dysfunction.

We first focused on combining Cd2ap heterozygosity with deficiency of the Src family tyrosine kinase Fyn. While Fyn+/− mice are
Figure 6
CD2AP SH3 domains interact directly with Synpo, but CD2AP does not interact with Nephi1. (A) FLAG-tagged Synpo (Synpo-long) was coexpressed with myc-tagged proteins, including full-length CD2AP (lane 1, CD2AP FL), CD2AP lacking the SH3 domains (lane 2, ΔSH3 domains), and CD2AP lacking the proline-rich domains (lane 3, ΔPR domains). Anti-FLAG immunoprecipitates were immunoblotted with an anti-myc antibody (upper panel). The expression of wild-type and mutated CD2AP proteins (input lysate; anti-myc) and Synpo is shown in the middle and lower panels, respectively. (B) FLAG-tagged Synpo (lane 1, FLAG–Synpo-long) and FLAG-tagged GFP (lane 2) were overexpressed, and anti-FLAG immunoprecipitates were blotted with recombinant, biotinylated GST-CD2AP fusion protein containing the 3 SH3 domains (left panel) or immunoblotted with anti-FLAG antibody (right panel). (C) FLAG-tagged GFP (lane 1, control), FLAG-tagged Synpo-long (lane 2), FLAG-tagged Synpo-short (lane 3), and FLAG-tagged Synpo-T (lane 4) were coexpressed with myc-tagged full-length CD2AP. Immunoprecipitates were prepared with an anti-FLAG antibody and immunoblotted with an anti-myc antibody (upper panel). (D) Nephi1–yellow fluorescent protein (Nephi1–YFP) was coexpressed with myc-tagged full-length CD2AP (lane 1) or myc-tagged nephrin (lane 2). Anti-myc immunoprecipitates were immunoblotted with anti-YFP antibody (upper panel). The expression of Nephi1–YFP input lysate and myc-tagged nephrin or CD2AP controls is shown in the middle and lower panels, respectively. (E) Nephi1–YFP (lane 1) and myc-nephrin (lane 2) were coexpressed with full-length FLAG-tagged CD2AP. Immunoprecipitates of FLAG–CD2AP were immunoblotted with anti-myc and anti-YFP antibodies. Nephi1–YFP or myc-nephrin input lysates (anti-myc, anti-YFP) and CD2AP expression are demonstrated in the middle and lower panels, respectively.

about 31% of Fyn−/− mice develop proteinuria by 12 months of age. This value, which is intermediate between the results of the 2 previous studies, suggests that other factors may be involved in the initiation and/or severity of proteinuria. However, the combination of CD2AP haploinsufficiency with Fyn deficiency clearly accentuated disease, as 100% of these animals developed proteinuria. A gene dosage effect was also apparent, since mice that were heterozygous for Cd2ap and null for Fyn developed proteinuria at a rate that was almost double the rate of combined Cd2ap+/− and Fyn−/− mice. Lastly, it should be noted that bigenic heterozygosity resulted in pathological changes that were not present in the Fyn−/− or CD2AP+/− mice.

Our experiments with the Synpo-deficient mice implicate, for what we believe is the first time, a role for Synpo in the pathogenesis of FSGS. Synpo is an actin-bundling protein that is specifically expressed in podocytes and in certain neurons in the brain (19). Synpo knockout mice exhibit neuronal defects but do not exhibit any spontaneous kidney abnormality (20, 21). Recently, the discovery of multiple Synpo isoforms and the fact that the shortest Synpo isoform (Synpo-T) is still expressed in the Synpo knockout suggest that this isoform might be compensating for the loss of the larger 2 isoforms in podocytes (20). The in vivo functionality of Synpo-T is not entirely clear, but in any case, our work establishes that Synpo-T is unable to fully compensate in the presence of CD2AP haploinsufficiency.

It should be emphasized that the relatively mild pathological changes seen here are partially related to the way the experiment was designed. We used proteinuria as the end-point and sacrificed mice as soon as proteinuria was confirmed. Since we screened mice only monthly, the variability of proteinuria and pathological changes may have been due to variable length of time proteinuria was present. When a few proteinuric animals were followed for several months, the proteinuria and pathological changes progressed rapidly, leading to renal dysfunction and a significant level of glomerulosclerosis.

These studies demonstrating genetic epistasis among CD2AP, Fyn, and Synpo imply that these proteins might interact with each other. We showed, for what we believe is the first time, endogenous associations of CD2AP with Synpo and Fyn. The association of Fyn...
with CD2AP is probably mediated by the SH3 domain of Fyn binding to proline sequences in CD2AP, as a previous report showed that the SH3 domains of Fyn, Src, and Yes could bind to CD2AP in vitro (29). Our study also demonstrated that Synpo and CD2AP form a protein complex. Mapping studies revealed that CD2AP and Synpo can directly interact and that this interaction is mediated by the SH3 domains of CD2AP, presumably by binding to proline-rich segments of Synpo. The fact that CD2AP binds to the nonoverlapping isoforms Synpo-short and Synpo-T suggests that there are at least 2 different proline-rich segments that can bind to CD2AP.

These data suggest that CD2AP, Fyn, and Synpo act in the same genetic pathway to maintain podocyte integrity. While the specific pathway is unclear, clues have emerged from the wide variety of proteins that are known to associate with CD2AP. For instance, CD2AP has been shown to interact with the slit diaphragm proteins podocin (30) and nephrin (31). A putative role for CD2AP in linking the slit diaphragm to the cortical actin cytoskeleton is suggested by associations of CD2AP with actin-capping protein (32), cortactin (33, 34), and the GTPase-activating protein for ADP-ribosylation factor (ARF) family G proteins, ASAP1 (35). CD2AP is also implicated in intracellular trafficking by its known interactions with proteins, such as synaptopodin, Rab4, and AP-2 (36, 37). A role for CD2AP in mediating ubiquitination and degradation in the lysosome is indicated by its known association with the ubiquitin ligase Cbl (38, 39).

In this study, we identified 2 new interacting partners for CD2AP, Fyn, and Synpo. As Fyn is known to tyrosine phosphorylate nephritic, it is exciting to speculate that the slit diaphragm is a type of signaling receptor and that CD2AP functions to orchestrate such complex processes as endocytosis and turnover of slit diaphragm components, establishment of cell polarity, and antiapoptotic signaling. The interaction between CD2AP and Synpo reinforces the idea that CD2AP plays a central role in regulating the actin cytoskeleton. We speculate that combined heterozygosity of CD2AP and many other proteins in the slit diaphragm signalsome may contribute to susceptibility to FSGS.

It is somewhat surprising that there are only a few published models where bigenic heterozygosity has been shown to directly lead to disease. These include congenital nonsyndromic hearing impairment (40), human insulin resistance (41, 42), inherited disorders of fatty acid β-oxidation (43), and polycystic kidney disease (44). To our knowledge, this is the first description of combined heterozygosity causing any kind of glomerular disease. Kozziell et al. reported a “trialectic” phenotype of 4 patients with homozygous mutations in either Nphs1 (nephrin) or Nphs2 (podocin), with an additional mutation in 1 allele of either Nphs1 (nephrin) or Nphs2 (podocin) (45). Genetic epistasis between nephrin and podocin is suggested by the combined effects of the 3 mutations (45). It is not clear, however, how the presence of the heterozygous allele influences the phenotype or the course of disease. But this reinforces the idea that the presence of additional mutations may play a role in susceptibility to FSGS.

The initial therapy for most cases of FSGS involves steroids or other potent immunosuppressants; however, the FSGS seen in established disease-causing mutations has typically been poorly responsive to steroids (46). Only a small fraction of the cases of steroid-resistant FSGS or familial FSGS have identified mutations (2). Thus, many of the remainder are likely to have some combinations of heterozygous mutations, as demonstrated in our models. The identification of such genes and alleles involved in familial FSGS will therefore aid the clinician in choosing which patients are likely to benefit from potentially toxic immunosuppressants. The future focus of glomerular diseases, such as FSGS, should expand from the evaluation of individual genes to the examination of the impact of many genes in combination. The use of combined mutational mouse models may allow us to identify genes that may act in concert with other genetic mutations to increase disease susceptibility.

**Methods**

**Materials and reagents.** The immortalized podocyte cell line has been described in detail (47). Synpo cDNA constructs (20), CD2AP- and nephrin-cDNA constructs (31) have been published previously. Antibodies to Synpo (20), to CD2AP (31), and to Fyn (48) have been described. Anti-Myc Tag (clone 4A6; Upstate USA Inc.), anti-FLAG M2-agarose (Sigma-Aldrich), monoclonal anti-GFP antibody (JL-8, BD Biosciences), protein G sepharose (Sigma-Aldrich), and Sulfo-NHS-LC-Biotin (Pierce Biotechnology) were purchased as indicated.

**Mice breeding.** CD2AP-deficient mice were maintained in our colony as heterozygotes and genotyped as previously described (12). CD2ap−/− mice were backcrossed (>10 generations) to a C57BL/6J background or maintained on a pure 129Sv background. Fyn-deficient mice were obtained from Jackson Laboratory, maintained on a C57BL/6J background in our laboratory, and genotyped per their published protocol. Synpo-deficient mice on a 129/Ola background (20) were genotyped as previously described (21). Neph1-deficient mice were obtained from Lexicon Genetics Inc. on a mixed 129/C57BL/6J-Tyr-cbd background and genotyped as previously published (11). Synpo/CD2AP and Fyn/CD2AP colonies were maintained on a pure 129 or C57BL/6J background, respectively. For all experiments, only littermates derived from the intercrossing of the 2 gene-deficient lines were used. In the case of the Neph1 and CD2AP intercrossing, we used colonies with a mixed C57BL/6J and 129Sv background. However, again we compared only littermates.

All animal studies reported here were approved by the Washington University Animal Studies Committee.

**Urine and serum proteins and creatinine.** Urine was collected monthly and tested for proteinuria using SDS-PAGE and known quantities of BSA as controls. An albumin concentration of 30 mg/dl was considered positive. Results correlated with measurements of urine protein performed using a Roche Cobas Mira Plus analyzer (Roche Diagnostics Corp.).

**Histology.** Mice were sacrificed within a month of scoring positive for proteinuria. After dissection, kidneys were rinsed in phosphate-buffered saline, fixed overnight in formalin, and submitted to the Histopathology Laboratory at Washington University Medical School for paraffin embedding, sectioning, and staining with PAS and H&E.

**Electron microscopy.** After dissection, renal cortex was fixed in 2.5% glutaraldehyde in 0.1 M Na cacodylate, stained in OsO4 dehydrated in ethanol, embedded in PolyBed 812 (Polysciences Inc.), sectioned on an ultramicrotome (Ultra Cut, Reichert-Jung), poststained in uranyl acetate and lead citrate, then viewed on a Zeiss 902 Electron Microscope in the Cell Biology Department of Washington University.

**Blood pressure measurements.** Mice were anesthetized with a 1.5% isoflurane/oxygen mixture administered with a vaporizer (Ohmeda Isotec 3, BOC Health Care). As previously described (49), we recorded heart rate and MAP by catheterizing the right common carotid artery with a Millar 1.4 French blood pressure probe and transducer (Millar Instruments Inc.) coupled to a PowerLab/4SP data-acquisition system (ADInstruments) and passing the probe into the ascending aorta.

**Communoprecipitation.** HEK 293T cells were transiently transfected with Lipofectamine (Invitrogen Corp.). After incubation for 24 hours, cells were

washed twice and lysed in a 1% Triton X-100 lysis buffer. To test the co-
munoprecipitation of nephrin and Nep1 with CD2AP, we used a lysis buffer
containing 1% digitonin (31). After centrifugation (15,000 g, 15 min,
4°C), cell lysates containing equal amounts of total protein were incubated
for 1 hour at 4°C with the appropriate antibody followed by incubation
with 40 μl of protein G sepharose beads for approximately 1 hour. The
beads were washed extensively with lysis buffer, and bound proteins were
resolved by 10% SDS-PAGE, transferred to nitrocellulose membranes, and
immunoblotted with specific antibodies. For coimmunoprecipitation of
dependous proteins, lysates were prepared from 293T cells, differentiated
mouse podocytes, or rat glomerular lysates. After centrifugation (15,000 g,
15 minutes, 4°C) and ultracentrifugation (100,000 g, 30 minutes, 4°C),
cell lysates containing equal amounts of total protein were precleared with
protein G sepharose and then incubated for 4°C with the indicated
antiserum, followed by incubation with 40 μl of protein G sepharose beads
for approximately 1 hour. The beads were washed extensively with
lysis buffer, and bound proteins were resolved by 10% SDS-PAGE.

Far Western blot. Immunoprecipitates of FLAG-tagged Synpo-long and
FLAG-tagged GFP as control were run on SDS-PAGE and then transferred
onto a nitrocellulose membrane. Blots were blocked in PBS–TWEEN
containing 5% BSA and then incubated with 100 μg/ml of biotinylated
CD2AP SH3 domains containing GST fusion protein in the blocking buf-
er at 4°C. The blots were probed with HRP-conjugated streptavidin and
then subjected to enhanced chemiluminescence.
