Niemann-Pick C1 protects against atherosclerosis in mice via regulation of macrophage intracellular cholesterol trafficking

Niemann-Pick C1 (NPC1) is a key participant in cellular cholesterol trafficking. Loss of NPC1 function leads to defective suppression of SREBP-dependent gene expression and failure to appropriately activate liver X receptor–mediated (LXR-mediated) pathways, ultimately resulting in intracellular cholesterol accumulation. To determine whether NPC1 contributes to regulation of macrophage sterol homeostasis in vivo, we examined the effect of NPC1 deletion in BM-derived cells on atherosclerotic lesion development in the Ldlr+/− mouse model of atherosclerosis. High-fat diet–fed chimeric Npc1+/− mice reconstituted with Ldlr+/−/Npc1+/− macrophages exhibited accelerated atherosclerosis despite lower serum cholesterol compared with mice reconstituted with wild-type macrophages. The discordance between the low serum lipoprotein levels and the presence of aortic atherosclerosis suggested that intrinsic alterations in macrophage sterol metabolism in the chimeric Npc1+/− mice played a greater role in atherosclerotic lesion formation than did serum lipoprotein levels. Macrophages from chimeric Npc1+/− mice showed decreased synthesis of 27-hydroxycholesterol (27-HC), an endogenous LXR ligand; decreased expression of LXR-regulated cholesterol transporters; and impaired cholesterol efflux. Lower 27-HC levels were associated with elevated cholesterol oxidation products in macrophages and plasma of chimeric Npc1+/− mice and with increased oxidative stress. Our results demonstrate that NPC1 serves an atheroprotective role in mice through regulation of LXR-dependent cholesterol efflux and mitigation of cholesterol-induced oxidative stress in macrophages.

Introduction

Macrophages regulate tissue lipid homeostasis through the uptake and catabolism of atherogenic plasma lipoproteins (1). Macrophages express scavenger receptor A and CD36, which bind and internalize modified lipoproteins, such as oxidized LDL. Upon internalization, lipoprotein–derived cholesterol is delivered to a late endosomal organelle, where cholesterol esters are hydrolyzed to free cholesterol. Delivery of free cholesterol from the endocytic pathway to the plasma membrane and ER requires the coordinated actions of the late endosomal Niemann-Pick C1 (NPC1) and lysosomal NPC2 proteins (2). Delivery of cholesterol to the ER rapidly stimulates esterification and accumulation of cholesterol ester in cytoplasmic droplets. Because the scavenger receptors, in contrast to the LDL receptor (LDLR), are not controlled by a sterol-regulated negative feedback loop, macrophages accumulate massive quantities of lipoprotein-derived lipids.

To prevent cytotoxicity caused by accumulation of excess cholesterol in macrophages, liver X receptors (LXRs), together with other members of the nuclear receptor superfamily, contribute to cellular cholesterol homeostasis by regulating genes that contribute to the storage, transport, and catabolism of sterols and their metabolites (1). LXRs respond to elevated cholesterol levels via transactivation of genes involved in sterol transport, cholesterol efflux and HDL metabolism, and sterol catabolism (3). Recent studies have shown that certain oxysterols, such as 27-hydroxycholesterol (27-HC), are specific ligands for the LXRs (4). 27-HC is enzymatically produced in macrophages in response to cholesterol loading and has been proposed to be an important physiological LXR ligand (5, 6). Indeed, fibroblasts from patients with cerebrotendinous xanthomatosis (CTX), a disorder caused by deficiency in sterol 27-hydroxylase and characterized by absence of 27-HC, exhibit altered sterol regulatory responses (7). CTX is also associated with premature atherosclerosis, although the precise contribution of reduced 27-HC levels to the atherosclerotic phenotype is unclear because the deficiency in 27-hydroxylase also perturbs bile acid synthesis and affects multiple metabolic nuclear receptor (e.g., LXR, farnesoid X receptor, and pregnane X receptor) signaling pathways.

Insight into the mechanisms underlying regulation of cellular cholesterol homeostasis has come from study of the NPC1 gene. Fibroblasts from NPC patients exhibit markedly impaired rates of esterification of LDL-cholesterol (8, 9) and mobilization of newly

expression and to promote LXR-mediated responses and are associated with impaired LDL–cholesterol–stimulated production of 25-HC and 27-HC (17, 18). Based on these findings, we previously proposed that NPC proteins normally regulate cholesterol homeostasis by channeling excess LDL-cholesterol to intracellular sites of oxysterol synthesis, such as the mitochondrial sterol 27-hydroxylase (CYP27A1), resulting in the generation of LDL-cholesterol–derived oxysterols (2).

To test whether NPC1-mediated cholesterol trafficking contributes to regulation of macrophage sterol homeostasis in the vessel wall and modulates susceptibility to atherosclerosis, we examined the effect of Npc1 deletion in BM-derived cells of chimeric mice on atherosclerotic lesion development. We showed that macrophage expression of NPC1 was critical for generation of an endogenous oxysterol LXR ligand and that NPC1 served an atheroprotective role through regulation of LXR-dependent cholesterol efflux and mitigation of cholesterol-induced oxidative stress.

Deletion of Npc1 in BM-derived cells alters serum lipoprotein levels

To determine the effect of loss of NPC1 expression on atherosclerotic lesion development, transplanted mice were maintained on a high-fat diet (0.15% cholesterol and 42% fat), which has previously been shown to promote lesion formation in Ldlr−/− mice (22), and euthanized after 10 weeks. Serum lipid levels were measured after 0, 3, 6, and 10 weeks of high-fat diet feeding, revealing significantly lower cholesterol and triglyceride (TG) levels at 6 and 10 weeks in the chimeric MφNpc1−/− mice compared to the wild-type mice (Table 1).

MφNpc1+/+ and MφNpc1−/− mice were fed high-fat diet for 10 weeks. Sera from 5–6 animals per genotype were pooled and separated by FPLC, and individual fractions were assayed for cholesterol and TG content. Data are mean ± SEM of triplicate determinations for each genotype. *P ≤ 0.005 versus MφNpc1+/+.

Results

Generation of mice with deletion of Npc1 in BM-derived cells. We generated mice with deletion of Npc1 in BM-derived cells using the BM transplant (BMT) strategy shown in Figure 1A. Npc1−/− mice (19) were first backcrossed 8 generations into Ldlr−/− mice, a genetically modified mouse line with increased susceptibility to atherosclerotic lesion development on a high-fat diet (20). The Ldlr−/− Npc1−/− mice were intercrossed with a congenic strain that harbors the Ly5.1 polymorphism to monitor reconstitution after BMT (21). In the transplanted mice, the mean reconstitution efficiency was 91.6% at 6 weeks (n = 122), demonstrating that the hematopoietic lineages were predominantly derived from the donor BM in the chimeric mice (Figure 1B). Repopulation with donor-derived macrophages was confirmed in peritoneal macrophages harvested from chimeric mice reconstituted with Ldlr−/− Npc1−/− macrophages (MφNpc1+/−) by staining for lysosomal accumulation of free cholesterol (Figure 1C), the hallmark of the NPC1 mutant phenotype (14).

Analysis of BM reconstitution of Ldlr−/− Npc1+/+ and Ldlr−/− Npc1−/− donors. (A) Transplantation scheme for generation of Ldlr−/− mice with BM-derived cells deficient in Npc1. (B) At 6 weeks after BMT, peripheral blood was obtained from recipients, and cells were stained with anti-CD45.1 and anti-CD45.2 to identify Ly5.1- and Ly5.2-positive cells by flow cytometry. Data represent 105 cells from each mouse. (C) Cholesterol staining of peritoneal macrophages harvested from high-fat fed MφNpc1+/+ and MφNpc1−/− chimeric mice. Arrowhead denotes cholesterol-laden lysosomes. Scale bar: 10 μM.

Generation of mice with deletion of Npc1 in BM-derived cells. We generated mice with deletion of Npc1 in BM-derived cells using the BM transplant (BMT) strategy shown in Figure 1A. Npc1−/− mice (19) were first backcrossed 8 generations into Ldlr−/− mice, a genetically modified mouse line with increased susceptibility to atherosclerotic lesion development on a high-fat diet (20). The Ldlr−/− Npc1−/− mice were intercrossed with a congenic strain that harbors the Ly5.1 polymorphism to monitor reconstitution after BMT (21). In the transplanted mice, the mean reconstitution efficiency was 91.6% at 6 weeks (n = 122), demonstrating that the hematopoietic lineages were predominantly derived from the donor BM in the chimeric mice (Figure 1B). with MφNpc1−/− mice (Figure 2A). Pooled serum lipoprotein profiles obtained from chimeric mice after 10 weeks on the high-fat diet demonstrated significant reductions in both cholesterol and TGs in the VLDL, LDL, and HDL fractions of MφNpc1−/− compared with MφNpc1+/+ mice (Figure 2B and Table 1). The lower serum lipoprotein levels in the MφNpc1−/− mice were not explained by differences in chow intake (data not shown), body weight (Figure 3A), fractional cholesterol absorption (MφNpc1−/+, 80.1% ± 0.62%; MφNpc1−/−, 82.8% ± 2.2%; P = NS), or rate of VLDL synthesis (Figure 3B). On the other hand, 125I-VLDL clearance was significantly accelerated in MφNpc1−/− mice compared with MφNpc1+/+ mice (Figure 3C) and was accompanied by a hepatic free cholesterol level 1.8-fold that of MφNpc1+/+ mice (Figure 3D). Examination of Kupffer cells, BM-derived cells of macrophage lineage located in the lumen of hepatic sinusoids, revealed free cholesterol levels 1.8-fold and cholesterol ester levels 1.9-fold those of MφNpc1+/+ mice (Figure 3E), consistent with the NPC phenotype. Because Kupffer cells represent about 10% of the total hepatic cell population, it is likely that the bulk of the cholesterol is present in hepatocytes and accumulates as a result of increased lipoprotein clearance.

*Increased aortic atherosclerosis in high-fat diet–fed MφNpc1−/− mice.* Despite lower serum lipids, aortic atherosclerosis was accelerated in the MφNpc1−/− mice after 10 weeks on the high-fat diet compared with MφNpc1+/+ mice (Figure 4, A and B). There was no evidence for a gene dosage effect with respect to susceptibility to atherosclerosis, because MφNpc1−/− and MφNpc1+/− mice exhibited nearly identical levels of aortic atherosclerosis. Aortic sinus sections in the MφNpc1−/− mice demonstrated markedly increased Oil red O staining for neutral lipid accumulation (Figure 4C). The aortic lesions in both MφNpc1−/− and MφNpc1+/− mice exhibited a high degree of cellularity with extensive macrophage infiltration, in agreement with an earlier report (23), and no changes were observed in the extent of macrophage apoptosis (data not shown). However, MφNpc1−/− mice did not exhibit the profound atherothrombotic phenotype previously observed in the whole-body Npc1−/−Apoe−/− mice (23). The discordance between the serum lipoprotein levels and aortic atherosclerosis suggested that intrinsic alterations in macrophage sterol metabolism in the MφNpc1−/− mice likely play a greater role in atherosclerotic lesion formation than do serum lipoprotein levels. Previous studies have shown that NPC1 mutant fibroblasts fail to induce ABCA1 mRNA and protein expression in response to cholesterol loading (16, 24) and exhibit impaired ABCA1- and ABCG1-mediated cholesterol transport, respectively (25). the block imposed by NPC1 loss of function. Taken together, our findings show that failure to activate LXR-mediated responses in macrophages from MφNpc1–/– mice may have contributed to atherosclerotic lesion formation.

LXR ligand deficiency in macrophages from MφNpc1–/– mice. Previously we showed that the sterol homeostatic defects in NPC1 mutant cells were associated with a profound decrease in synthesis of LDL-cholesterol-derived oxysterols (17, 18). To assess whether decreased production of 27-HC, an endogenous LXR ligand, causes reduced LXR-mediated cholesterol efflux, we measured oxysterol production in peritoneal macrophages in response to acetylated LDL (AcLDL) cholesterol loading. While mRNA levels of CYP27A1, the mitochondrial sterol 27-hydroxylase responsible for conversion of cholesterol to 27-HC, were equivalent in macrophages isolated from MφNpc1+/+ and MφNpc1–/– mice (data not shown), synthesis of 27-HC and its oxidation product, cholestenoic acid, were reduced in Npc1–/– macrophages by 52% and 64%, respectively (P < 0.05; Figure 6A). Similar reductions in 27-HC synthesis were observed in non-lipoprotein-fed Npc1–/– macrophages (data not shown), indicating that lipoprotein-associated oxysterols did not substantially contribute to 27-HC levels. Moreover, in the plasma of high-fat diet–fed MφNpc1–/– mice, total 27-HC levels were reduced by 43% (MφNpc1+/+, 541 ± 2.5 ng/ml; MφNpc1–/–, 310 ± 0.34 ng/ml; P < 0.05), and free 27-HC levels were reduced by 24% (MφNpc1+/+, 145 ± 5.5 ng/ml; MφNpc1–/–, 111 ± 2.4 ng/ml; P < 0.05; Figure 6B). Total plasma 27-HC is representative of the vast majority of 27-HC that is esterified and lipoprotein-associated, whereas free 27-HC is more representative of the non–lipoprotein-associated 27-HC (25, 26). In light of the rapid hepatic uptake of free 27-HC, the reduced circulating levels of free 27-HC in MφNpc1–/– mice likely reflect lower rates of 27-HC synthesis by tissue macrophages, the principal source of circulating 27-HC (27), and not simply lower serum lipoprotein levels.

Increased oxidative stress in Npc1–/– macrophages. In addition to the deficiency in enzymatic synthesis of 27-HC, Npc1–/– mice tissues exhibit increased nonenzymatic oxidation (i.e., autoxidation) of cel-
ular cholesterol, resulting in a several-fold increase in total cholesterol oxidation products (28). Autodioxidation products, which include steroid ring-modified 5,6- and 7-oxygenated compounds (29), have been reported to be cytotoxic in vitro and proposed to contribute to atherogenesis (30). We therefore monitored for the presence of the cholesterol oxidation products in the plasma of M\textsubscript{\(\phi\)}Npc1\textsuperscript{+/-} and M\textsubscript{\(\phi\)}Npc1\textsuperscript{-/-} mice and in conditioned media and cell extracts of lipoprotein-fed peritoneal macrophages harvested from the chimeric mice. Total cholesterol-3\beta,5\alpha,6\beta-triol (an oxidation product of both 5\alpha,6\alpha-epoxycholesterol and 5\beta,6\beta-epoxycholesterol), 7\beta-HC, and 7-ketocholesterol levels in plasma from M\textsubscript{\(\phi\)}Npc1\textsuperscript{-/-} mice were respectively 3.7-, 2.2-, and 1.15-fold those of M\textsubscript{\(\phi\)}Npc1\textsuperscript{+/-} mice (\(P < 0.05\); Figure 7A). Levels of cell-associated oxysterols in M\textsubscript{\(\phi\)}Npc1\textsuperscript{-/-} macrophages were uniformly elevated for all oxysterols examined (Figure 7B), even among enzymatically generated side-chain oxysterols 24-HC, 25-HC, and 27-HC, for which total oxysterol synthesis (media plus cell-associated oxysterols) was reduced (Figure 6A). For the oxysterol panel measured in the cell extracts, total cellular oxysterols were 3.67 \(\mu\)g/mg protein in Npc1\textsuperscript{-/-} macrophages, compared with 1.42 \(\mu\)g/mg protein in M\textsubscript{\(\phi\)}Npc1\textsuperscript{+/-} macrophages, consistent with the oxysterol accumulation previously reported in Npc1\textsuperscript{-/-} murine tissues (28). The intracellular accumulation of oxysterols may reflect impaired oxysterol efflux due to reduced expression of LXR-activated sterol transporters. Recent reports showing that 7-ketocholesterol, 25-HC, and 27-HC accumulate in ABCG1-, ABCA1-, and ABCG1/ABCG4-deficient cells, respectively, support such a mechanism (31–33). Whether the elevated levels of nonenzymatic cholesterol autoxidation products, which have been shown to be cytotoxic in vitro, also contribute to atherogenesis in vivo, or are simply markers of oxidative stress, is not known.

Cholesterol autoxidation products are formed through the interaction of cholesterol with ROS (34). To determine whether increased ROS generation is responsible for the elevated oxysterol levels in the Npc1\textsuperscript{-/-} macrophages, we measured cell fluorescence following loading with 6-carboxy-2',7'-dichlorodihydrofluorescein diacetate (H\textsubscript{2}DCFDA), a fluorescent, membrane-permeable probe widely used as a marker of ROS in cells (35). We found increased ROS generation in the M\textsubscript{\(\phi\)}Npc1\textsuperscript{-/-} macrophages, 2.2-fold that of M\textsubscript{\(\phi\)}Npc1\textsuperscript{+/-} macrophages, indicative of increased cellular oxidative stress (Figure 7C). Protein carbonyl levels, a marker of cumulative oxidative stress, were nearly 2-fold those of M\textsubscript{\(\phi\)}Npc1\textsuperscript{-/-} macrophages, providing further support for increased ROS generation in M\textsubscript{\(\phi\)}Npc1\textsuperscript{-/-} cells (Figure 7D). Treatment with T0901317, a synthetic oxysterol LXR ligand previously shown to upregulate ABCA1 expression and cholesterol efflux in Npc1\textsuperscript{-/-} fibroblasts (24, 36), reduced ROS accumulation by 38%, partially suppressing oxidative stress in the M\textsubscript{\(\phi\)}Npc1\textsuperscript{-/-} macrophages (Figure 7C).

**Discussion**

In this study we investigated the role of NPC1-mediated cholesterol trafficking in regulation of macrophage cholesterol homeostasis. Using BMT to disrupt NPC1 expression in macrophages of Ldlr\textsuperscript{-/-} mice, we demonstrated that absence of NPC1 expression was proatherogenic in vivo. Deletion of Npc1 in BM-derived cells accelerated atherosclerosis by impairing cholesterol efflux and promoting cellular oxidative stress. The Npc1\textsuperscript{-/-} chimeric mice exhibited increased atherogenic lesion formation despite lower cholesterol and TG levels in the VLDL and LDL fractions. The discordance observed between serum cholesterol and the extent of atherosclerosis underscores the central role of the NPC cholesterol trafficking pathway in regulation of macrophage lipid metabolism and modulating the susceptibility of these cells to oxidative stress.

Previous studies have shown that Npc1\textsuperscript{-/-} cells in culture have impaired cholesterol efflux. The lysosomal sequestration of LDL-
derived cholesterol affects efflux activity by limiting cholesterol substrate for ABCA1-dependent efflux and by failing to appropriately generate LDL-cholesterol-derived side-chain oxysterols (15, 17, 18). In Npc1–/– cells, decreased production of side-chain oxysterols, which serve as endogenous LXR ligands, results in reduced ABCA1 protein expression and lower cholesterol efflux activity (16, 24). Thus, in cultured cells NPC1-mediated cholesterol trafficking participates in regulation of LXR sterol homeostatic responses. In the present study, we provide evidence that the NPC1 cholesterol trafficking pathway regulates LXR-dependent cholesterol efflux in vivo, alleviating cholesterol-induced oxidative stress and serving an atheroprotective role.

While the function of NPC1 in distribution of free cholesterol from the late endocytic pathway is well characterized, little is known of the macrophage-specific role of NPC1 in regulating sterol homeostasis in vivo and in modulating susceptibility to atherosclerosis. A previous study that examined the effect of Npc1 deficiency on atherogenesis did not find differences in aortic lesion area in high-fat diet–fed Npc1+/– ApoE–/– mice compared with ApoE–/– mice, although NPC1 heterozygosity was associated with resistance to lesional necrosis and lesional macrophage apoptosis (37). More recently, Welch et al. reported that introduction of the Npc1–/– mutation into the ApoE–/– background predisposed to increased lesion formation and atherothrombosis (23). In agreement with these studies, we found that NPC1

Figure 5
Reduced expression of cholesterol transporters and cholesterol efflux in Mφ Npc1–/– chimeric mice. (A) Abca1 and Abcg1 gene expression in peritoneal macrophages harvested from high-fat diet–fed Mφ Npc1+/+ and Mφ Npc1–/– mice. Expression was determined by real-time quantitative RT-PCR and normalized to expression in Mφ Npc1+/+ macrophages. loss of function, but not NPC1 haploinsufficiency, promoted aortic atherosclerosis in mice fed the high-fat diet. We further extended these earlier reports by demonstrating the selective role of Npc1−/− BM-derived cells to the proatherosclerotic phenotype and by elucidating the contribution of the NPC cholesterol trafficking pathway in vivo to LXR-dependent cholesterol efflux in macrophages. Given the high level of NPC1 expression in the monocyte/macrophage lineage and the importance of these cells to lipoprotein metabolism, it is probable that deletion of Npc1 in macrophages is primarily responsible for the accelerated atherosclerosis, although the contribution of non-macrophage BM-derived cells cannot be excluded. Because complete disruption of NPC1 expression is required to increase susceptibility to atherosclerosis, we conclude that the protective effect of NPC1-mediated cholesterol trafficking is not gene dose dependent.

We propose that decreased mitochondrial conversion of lipoprotein cholesterol to 27-HC in the Npc1−/− macrophages is the principal mechanism for accelerated atherosclerosis in the MφNpc1−/− model. Decreased 27-HC levels, which have been reported previously in other Npc1−/− cell types (17, 18), may reflect impaired delivery of cholesterol substrate to the inner mitochondrial membrane for side-chain oxysterol synthesis. However, recent reports showing that mitochondrial membranes in Npc1−/− cells are enriched in cholesterol (38, 39) indicate that the consequence of NPC1 loss of function may be more complex than failure of bulk cholesterol delivery to the mitochondria. Despite the endosom al cholesterol trafficking defect, cholesterol transport to mitochondria is enhanced in Npc1−/− cells, leading to inhibition of ATP synthase activity (38). Free cholesterol loading of the mitochondria could prevent transfer of cholesterol from the outer to inner mitochondrial membranes, where oxysterol synthesis occurs, or could inhibit sterol 27-hydroxylase enzymatic activity directly. It is likely that the lower 27-HC levels observed in Npc1−/− macrophages result from decreased oxysterol synthesis rather than enhanced catabolism of 27-HC, because we did not observe a commensurate increase in the levels of known oxidation products of 27-HC, such as cholestenoic acid (Figure 6A), or of 7α,27-HC or 7β,27-HC (ref. 40 and data not shown). In Npc1−/− macrophages, deficiency of 27-HC, which is known to activate LXR gene expression and has been proposed as an endogenous LXR ligand (4–6), is associated with decreased expression of the ABCA1 and ABCG1 sterol transporters, impaired cholesterol efflux, and lower serum HDL levels. Therefore, in the Npc1−/− macrophages, we conclude that 27-HC deficiency is responsible for decreased LXR activation and contributes to atherosclerotic lesion formation by failing to stimulate cellular cholesterol efflux. To the best of our knowledge, our findings are the first to implicate deficiency of an endogenous LXR ligand in vivo in the development of atherosclerosis.

Our findings support a central role for NPC1 in macrophage reverse cholesterol transport. By directing a portion of the lipoprotein-derived cholesterol to sites of oxysterol synthesis, the NPC pathway is responsible for generation of endogenous LXR ligands that govern expression of the ABCA1 and ABCG1 cell surface sterol transporters. In macrophages, ABCA1 and ABCG1 act in concert to facilitate reverse cholesterol transport initially through lipidation of nascent apoA-I, followed by its subsequent remodeling into mature, spheroidal HDL (41). In previous BMT studies, combined deletion of ABCA1 and ABCG1 led to a massive lipid accumulation in macrophages that was far more dramatic than occurred...
with deletion of either ABCA1 or ABCG1 alone (42–46). Thus, the profound atherosclerotic phenotype in the mice with deletion of Npc1 in BM-derived cells appears to reflect the upstream role of the NPC cholesterol trafficking pathway for induction of these LXR-activated sterol transporters.

Increased oxidative stress in the Npc1–/– macrophages may also have contributed to atherosclerotic lesion formation in vivo. The etiology of elevated ROS generation and oxidative damage in the Npc1–/– macrophages does not appear to relate to ER stress, because no increase was found in expression of ER stress markers grp78, calreticulin, or CCAAT/enhancer-binding protein homologous protein (CHOP) (data not shown). Rather, increased ROS may be a consequence of free cholesterol–mediated mitochondrial dysfunction and other oxysterol species potentially could serve as novel biomarkers to facilitate early detection and stratification of human subjects at risk for atherosclerotic disease. In addition to inhibition of ATP synthase activity and loss of membrane potential, cholesterol accumulation in mitochondrial membranes is associated with mitochondrial glutathione depletion, which sensitizes cells to oxidative stress (38, 39). ROS generated by oxidative stress are a well-established signal for activation of NF-kB, a key transcription factor in the induction of inflammatory mediators (47). Thus, induction of NF-kB–dependent pathways, possibly involving lipoprotein oxidation and inflammatory cell recruitment, may have accelerated atherosclerosis in the chimeric MφNpc1–/– model (48).

Under conditions of cholesterol excess, the mitochondria likely serve as an important link between LXR-dependent pathways and modulation of oxidative stress in macrophages. In Npc1–/– macrophages, decreased oxysterol synthesis by the mitochondrial sterol 27-hydroxylase resulted in failure to activate LXR-dependent gene expression and cholesterol efflux, further exacerbating free cholesterol–induced mitochondrial dysfunction and promoting oxidative stress. The accumulation of cholesterol autoxidation products in the Npc1–/– macrophages may be caused not only by the highly oxidative intracellular milieu, but also by decreased oxysterol export by the LXR-regulated ABCA1 sterol transporter (31). An unexpected finding in our study was that treatment with the synthetic LXR ligand attenuated ROS generation. These results suggest that pharmacological activation of LXR pathways in macrophages provides atheroprotection both by lowering cellular cholesterol and by suppressing mitochondria-mediated oxidative stress.

Because human NPC1 disease is a rare disorder that is generally fatal in the first 2 decades of life, the incidence of atherosclerotic disease in affected individuals or in obligate heterozygotes is not known. Given the pathophysiological effects of disruption of NPC1 function in macrophages, we speculate that polymorphisms in the NPC1 gene may modulate atherosclerosis susceptibility. In light of our findings that plasma 27-HC levels correlated with impaired 27-HC synthesis in the cultured macrophages, detection of altered circulating levels of this proposed physiological LXR ligand (5, 6) may provide important insight into cholesterol metabolism in the vessel wall. In particular, plasma levels of 27-HC and other oxysterol species potentially could serve as novel biomarkers to facilitate early detection and stratification of human subjects at risk for atherosclerotic disease.

Methods

Mice. BALB/c Npc1+/+ mice were obtained from The Jackson Laboratory, backcrossed 8 generations into the C57BL/6 background, and then intercrossed with C57BL/6 Ldlr–/– Ly5.1 mice to generate BMT donors with the following genotypes: Npc1–/–Ldlr–/– Ly5.1, Npc1+/–Ldlr–/– Ly5.1, and Npc1+/–Ldlr–/– Ly5.1. Experimental procedures were approved by the Washington University Animal Studies Committee and were conducted in accordance with the USDA Animal Welfare Act and the Public Health Service Policy for the Humane Care and Use of Laboratory Animals.

BMT. BM was harvested from sex-matched Npc1–/–Ldlr–/– Ly5.1, Npc1+/–Ldlr–/– Ly5.1, and Npc1+/–Ldlr–/– Ly5.1 donors by flushing the femurs and tibias with PBS. Male C57BL/6 Ldlr–/– Ly5.2 recipients (4–6 weeks old) were lethally irradiated with 10 Gy from a 137Cs source, followed by tail vein injection with 106 BM cells. Prophylactic antibiotics (sulfamethoxazole and trimethoprim) were administered for 2 weeks after BMT. At 6 weeks after BMT, peripheral blood was obtained from recipients, and cells were stained with anti-CD45.1 and anti-CD45.2 to identify Ly5.1- and Ly5.2-positive cells by flow cytometry, as previously described (21), to evaluate the reconstitution.

High-fat diet feeding. Transplanted mice with greater than 75% reconstitution were placed on a high-fat diet containing 0.15% cholesterol and providing 42% calories as fat (TD 88137; Harlan Teklad). Serum cholesterol and TG measurements were performed at 0, 3, 6, and 10 weeks after initiation of high-fat diet feeding. Mice were fasted for 4 hours prior to blood draws. Sera of mice fed the high-fat diet for 10 weeks were pooled to obtain lipoprotein profile by fast protein liquid chromatography (FPLC) (49). High-sensitivity lipoprotein profiling was performed using the Liposcan method by Skylight Biotech Inc. (50).

Atherosclerotic lesion quantification. Lesion area was determined as described previously (51). Digital images of pinned aortas were analyzed using an image-processing program. Lesional areas were determined as the percentage of involvement of the intimai surface area for the arch (extending from the aortic valve to a point just distal to the left subclavian artery), the thoracic aorta (extending to the last intercostal artery), and the abdominal aorta (extending to the iliac bifurcation).

Immunocytochemistry. Hearts were frozen in Tissue-Tek OCT compound, and sections were obtained through the aorta root. Frozen sections were fixed with acetone, and immunohistochemistry was performed as described previously (49). Sections were stained with Oil red O and Mac-3 to detect neutral lipids and macrophages, respectively. Cholesterol staining of peritoneal macrophages was performed using BC-φ, a FITC-conjugated derivative of perfluorocyanin O (φ toxin) (52).

Lipoprotein metabolism. VLDL clearance was performed as described previously (53). Briefly, VLDL was obtained from pooled donor Ldlr–/– mice and labeled with 125I to produce 125I-VLDL. Unincorporated 125I was removed with PD-10 columns, and FPLC was used to isolate the VLDL-specific fraction. Mice were anesthetized and injected with a 0.2-ml bolus of 125I-VLDL, and blood was subsequently collected at regular intervals. Data at each time point are presented as the mean from at least 3 different animals. VLDL synthesis rates were determined by inhibiting intravascular lipolysis with Triton WR 1339 (54). After measurement of baseline TGs, fasted mice were injected with WR 1339 (60 mg/kg) or PBS, and serum TGs were determined at 30, 60, and 120 minutes.

Cholesterol absorption assay. For cholesterol absorption studies, mice were maintained on cholesterol-deficient chow diet for 2 days before gavage with 0.1 ml soybean oil containing 0.0625 mg d1-sitostanol and 0.25 mg d1-cholesterol. Feces were collected for 3 days. Sterols were purified from feces and measured by gas chromatography/mass spectrometry (GC/MS) as described previously (55). The percent of d1-cholesterol in the stool was calculated from each tracer recovered relative to the respective total amount administered.

Kupffer cell isolation. Kupffer cells were isolated from liver tissue using a 2-step collagenase-dispase perfusion method as previously described (56).

Real-time quantitative RT-PCR. RNA isolation, cDNA synthesis, and real-time PCR using SYBR Green Master Mix with template-specific primers
was performed as described previously (24). Fold changes in gene expression were determined by normalization to 36B4 expression.

Cholesterol efflux assay. Thiglycolate-elicted peritoneal macrophages were harvested as described previously (57). Macrophages were incubated with [3H]cholesterol-labeled AcLDL, followed by incubation for 4 hours in medium containing 0.2% BSA and 10 μg/ml human apoA-I or 50 mg/ml human HDL. ApoA-I- and HDL-specific cholesterol efflux was calculated as the radioactivity released from the cells into the medium, expressed as a percentage relative to total radioactivity in cells and media.

Oxysterol determinations. Thiglycolate-elicted peritoneal macrophages were harvested as described above. Macrophages were grown in DMEM plus 10% FBS for 4 hours and then changed to DMEM with 10% lipoprotein-deficient serum. Macrophages were refed DMEM with 10% lipoprotein-deficient medium containing 50 μg/ml AcLDL overnight, followed by harvest of medium and cells for lipid extraction. Oxysterols were extracted from the media and measured by GC/MS as previously described using 200 pmol deuterated 27-HC (d3) at room temperature) prior to oxysterol isolation to hydrolyze sterol esters.

8. Steinberg, S.J., Mondal, D., and Fensom, A.H. 1996. identification, except that the total samples underwent saponification (1 hour medium containing 0.2% BSA and 10 μg/ml human HDL. ApoA-I- and HDL-specific cholesterol efflux were calculated as the radioactivity released from the cells into the medium, expressed as a percentage relative to total radioactivity in cells and media.

Oxysterol determinations. Thiglycolate-elicted peritoneal macrophages were harvested as described above. Macrophages were grown in DMEM plus 10% FBS for 4 hours and then changed to DMEM with 10% lipoprotein-deficient serum. Macrophages were refed DMEM with 10% lipoprotein-deficient medium containing 50 μg/ml AcLDL overnight, followed by harvest of medium and cells for lipid extraction. Oxysterols were extracted from the media and measured by GC/MS as previously described using 200 pmol deuterated 27-HC (d3) at room temperature) prior to oxysterol isolation to hydrolyze sterol esters (58). Oxysterol determinations were performed as described above.

Detection of ROS. Cellular levels of ROS were determined as previously described (35). Peritoneal macrophages were harvested as described previously (57) and plated in DMEM plus 10% FBS. Cells were washed in PBS and incubated for 30 minutes with PBS containing 0.5 mM MgCl2, 0.92 mM CaCl2, and 10 μM H2DCFDA. Fluorescence was determined using a fluorescent plate reader.

Measurement of protein carbonylation. Macrophages were harvested as described above. Detection of the formation of carbonyl groups in proteins was performed according to the manufacturer’s instructions using the OxyBlot oxidized protein detection kit (Chemicon International).

Results. Statistics are expressed as mean ± SEM. The statistical significance of differences in mean values was determined by single-factor ANOVA or Student’s t test. A P value of 0.05 or less was considered significant.
