Mutations in the genes PTEN-induced putative kinase 1 (PINK1), PARKIN, and DJ-1 cause autosomal recessive forms of Parkinson disease (PD), and the PINK1/Parkin pathway regulates mitochondrial integrity and function. An important question is whether the proteins encoded by these genes function to regulate activities of other cellular compartments. A study in mice, reported by Xiong et al. in this issue of the JCI, demonstrates that PINK1, Parkin, and DJ-1 can form a complex in the cytoplasm, with PINK1 and DJ-1 promoting the E3 ubiquitin ligase activity of Parkin to degrade substrates via the proteasome (see the related article beginning on page 650). This protein complex in the cytosol may or may not be related to the role of these proteins in regulating mitochondrial function or oxidative stress in vivo.

Parkinson disease (PD) is the second most common neurodegenerative disorder, and mutations in the genes PTEN-induced putative kinase 1 (PINK1, also known as Parkinson disease 6 [PARK6]), PARKIN (also known as PARK2), and DJ-1 (also known as PARK7) cause autosomal recessive forms of PD/parkinsonism. PINK1 encodes a protein with a mitochondrial targeting sequence and a putative serine/threonine kinase domain, and PINK1 is predominantly localized to mitochondria (1). The Parkin protein contains two RING finger motifs, has E3 ubiquitin ligase activity in vitro, and is largely localized to the cytosol (1). The endogenous DJ-1 protein is found in mitochondria and cytosol, but the function of DJ-1 is not entirely clear (1). Studies on the functions of these genes may provide important insights into PD pathogenesis.

Prior studies on protein degradation

Most PD patients have intraneuronal inclusions in the form of ubiquitin-positive Lewy bodies and Lewy neurites. Given the presence of Parkin in Lewy bodies and the putative role of Parkin as an E3 ligase, much of the initial work on Parkin was focused on its potential role in regulating protein degradation via the ubiquitin-proteasome system (UPS). Ubiquitination is accomplished by covalently linking the ubiquitin polypeptide (Ub) to a lysine residue in a specific protein substrate and requires the sequential action of an E1 activating enzyme, an E2 conjugating enzyme, and an E3 ligase (2). E3 ubiquitin ligases can mediate monoubiquitination (the addition of a single Ub to the substrate protein), multiubiquitination (the addition of multiple single UbS to different lysine residues in a target protein), and polyubiquitination (in which chains of four or more UbS are formed by the linkage of Ub molecules to lysine residues in other Ub molecules) (2). These linkages are most often to lysine 48 (K48) or lysine 63 (K63) of the Ub polypeptide. Proteins to be degraded by the proteasome are largely K48 polyubiquitinated. In contrast, K63 polyubiquitination, as well as monoubiquitination and multibiquitination, primarily function in non-degradative processes including signal transduction, transcriptional regulation, protein localization, and membrane trafficking (2).

Previous studies suggested that Parkin could function as an E3 ligase for protein/proteasome-mediated protein degradation (3). A handful of substrates of Parkin, including Parkin itself and an α-synuclein–interacting protein (Synphilin-1) (4), have been identified in vitro. If Parkin were indeed important in the degradative pathway in vivo, one would expect that the levels of its substrates should increase in Parkin-knockout mice. Unexpectedly, however, most of the substrates studied, including Synphilin-1, did not accumulate in Parkin-null mice (5). In addition, several studies have revealed that Parkin preferentially catalyzes monoubiquitination and K63-linked polyubiquitination of substrates including Synphilin-1 (6–8). These latter observations may offer potential explanations for the lack of substrate accumulation in vivo by implicating Parkin in a non-degradative, proteasome-independent process. Studies in Drosophila and more recently in mammals have provided important insights into Parkin function, although whether Parkin possesses degradative or non-degradative functions remains to be determined.

Central role of mitochondrial function in PD pathogenesis

Flies lacking Parkin function show striking defects in mitochondrial morphology that are highly similar, if not identical, to those observed in Pink1 mutants (9–11). Genetic epistasis experiments have demonstrated that Parkin and Pink1 act in a common genetic pathway, with Pink1 positively regulating Parkin (9, 10). This Pink1/Parkin pathway controls mitochondrial integrity at least in part via promotion of mitochondrial fission and/or inhibition of mitochondrial fusion (12–14). Consistent with these findings in Drosophila, patients with PINK1 or PARKIN mutations have indistinguishable clinical features and also show mitochondrial defects (1, 15). Recent studies also suggest that Pink1 and Parkin regulate mitochondrial functions in mammals (16–19). These findings underscore the central importance of the Pink1/Parkin pathway in regulating mitochondrial integrity and function.

Parkin is localized largely in the cytosol, though it can be found within mitochondria or associated with the outer mitochondrial membrane in certain contexts (20–22). Meanwhile, Pink1 has been found within mitochondria in cells and in vivo (9, 23, 24). The mechanism by which Parkin

Revisiting protein degradation in the cytosol

In this issue of JCI, Xiong and colleagues report a possible mechanism by which Parkin, Pink1, and DJ-1 might function outside of mitochondria in mice (26). Previous work had suggested that Pink1 binds to DJ-1 (27), DJ-1 binds to Parkin (28), and Pink1 binds to Parkin (1, 29). Here, Xiong et al. extend these observations by showing that the 3 proteins co-fractionate in gel filtration assays and co-immunoprecipitation in vivo. These interactions were observed largely in the cytosol, rather than in the mitochondria. Moreover, when Pink1 or DJ-1 are overexpressed or provided directly in vitro, ubiquitination and degradation of Parkin substrates (Synphilin-1 and Parkin itself) via the UPS pathway were enhanced, while levels of ubiquitinated Parkin decreased in pink1-mutant brain slice culture. The authors also show that pathogenic mutants of Pink1 and Parkin impaired the activity of the Parkin/Pink1/DJ-1 (PPD) complex, providing a potential mechanistic basis for how mutations in these proteins lead to PD pathogenesis. Based on these observations, the authors propose that Pink1, Parkin, and DJ-1 form a novel, cytoplasmically localized E3 ligase complex (the PPD complex) in which Pink1 and DJ-1 modulate Parkin-dependent ubiquitination and subsequent degradation of substrates. The authors also suggest that the PPD complex promotes the degradation of unfolded proteins. This conclusion is based largely on the observation that heat shock stress to cells in culture (which is presumed, though not shown, to cause misfolding of Parkin) resulted in increased ubiquitination and accumulation of Parkin, an effect that was suppressed when Pink1 was overexpressed. These results are intriguing, but heat shock is likely to alter the folding of many proteins and to affect the activity of myriad signaling pathways. Thus it is unclear whether the observed effects reflect direct interactions between Pink1, Parkin, and unfolded substrates. It will be particularly interesting to follow the fate of specific proteins known to be misfolded, when added to otherwise unperturbed cellular systems in which levels and activities of Pink1 and Parkin have been altered.

Possible connections between mitochondrial dysfunction and protein degradation?

How might the function of the PPD complex be related to the established roles of Pink1 and Parkin in regulating mitochondrial integrity and function? It is possible that the roles of Pink1/Parkin in regulating mitochondrial function are related to the potential degradative functions of the PPD complex (Figure 1A, A and B). DJ-1 can be recruited to the mitochondrial outer membrane following oxidative stress (30). Upon mitochondrial uncoupling, overexpressed Parkin can also be selectively recruited onto impaired mitochondria, promoting their removal through autophagy (31). If the kinase domain of Pink1 does indeed face the cytoplasm (25), Parkin and DJ-1 might be recruited to the mitochondrial surface under certain conditions and may thereby interact with Pink1 at the mitochondrial outer membrane (Figure 1A). Perhaps this interaction facilitates the ubiquitin ligase activity of Parkin, thereby promoting the turnover of molecules that regulate mito-

Figure 1
Three models for the role of the PPD complex. In this issue of the JCI, Xiong et al. report that Pink1, Parkin, and DJ-1 bind to each other and form a PPD E3 ligase complex in which Pink1 and DJ-1 modulate Parkin-dependent ubiquitination and subsequent degradation of substrates via the proteasome (26). Previous work suggests that the Pink1/Parkin pathway regulates mitochondrial integrity and promotes mitochondrial fission in Drosophila (9–14). (A) Parkin and DJ-1 may be recruited to the mitochondrial outer membrane during stress (30, 31) and interact with Pink1. These interactions may facilitate the ligase activity of Parkin, thereby facilitating the turnover of molecules that regulate mitochondrial dynamics and mitophagy. The PPD complex may have other roles in the cytosol that result in degradative ubiquitination (26) and/or relay information from mitochondria to other cellular compartments. (B) Alternatively, Pink1 may be released from mitochondria after cleavage to interact with DJ-1 and Parkin in the cytosol. A and B differ in the site of action of the PPD complex and the cleavage status of Pink1. The complex forms on the mitochondrial outer membrane potentially containing full-length Pink1 in A, and in the cytosol with cleaved Pink1 in B. The question marks indicate speculative connections. Note that lack of DJ-1 function results in phenotypes that are distinct from the mitochondrial phenotypes observed in null mutants of Pink1 or Parkin in Drosophila (9, 10, 12, 13, 34). Thus, although the PPD complex is illustrated here as regulating mitochondrial fission, the role of DJ-1 in vivo remains to be clarified. (C) It is also possible that the action occurs in the cytosol and is independent of the function of Pink1/Parkin in regulating mitochondrial integrity and function.
chondrial dynamics and mitophagy. A complication with this model, however, is that Xiong and colleagues report that while full-length Pink1 localized to mitochondria, a processed fragment of Pink1 was found predominantly in the cytoplasm, with this latter fragment being the version of Pink1 that predominantly interacts with Parkin (26). Similar cytotoxic Pink1 fragments have been reported in earlier studies (32), suggesting a model in which Pink1 is cleaved and released from mitochondria under certain stress conditions. Cleaved forms of Pink1 may thus be able to interact with Parkin in the cytosol and thereby promote degradative ubiquitination or other cellular processes (Figure 1B). Pink1-dependent activities in the cytoplasm may still serve to regulate mitochondrial function, for example by relaying information about mitochondrial status to other cellular compartments. The fact that a PD-causing mutation in the PINK1 kinase domain, G309D, compromises both the PPD complex with Parkin and DJ-1 (Figure 1C). It is important to note that loss of DJ-1 results in phenotypes that are distinct from the mitochondrial defects associated with loss of Pink1/Parkin in Drosophila muscle and male germline (33) is consistent with the hypothesis that the PPD complex may regulate mitochondrial function. Alternatively, cytotoxic Pink1 may carry out mitochondrial-independent functions, perhaps also in complex with Parkin and DJ-1 (Figure 1C). It is important to note that loss of DJ-1 results in phenotypes that are distinct from the mitochondrial defects associated with loss of Pink1/Parkin in Drosophila (9, 10, 34). If DJ-1 is an obligatory component of this complex, these in vivo results would suggest that the PPD complex is not essential for regulation of mitochondrial integrity. Future experiments are needed to clarify the role of DJ-1 function.

Summary

In summary, while the current study by Xiong et al. (26) rekindles enthusiasm for exploring the roles of Parkin in mediating protein degradation via the UPS, it remains to be shown whether Parkin, in complex with Pink1 and DJ-1, carries out protein degradation in vivo. It will be particularly important to reconcile the observation by the authors that the PPD complex degrades Synphilin-1, with the in vivo observations demonstrating that Synphilin-1 levels do not accumulate in knockout mice lacking Parkin (5). Perhaps the PPD complex only functions to regulate Synphilin-1 levels when cells are stressed, but not under the conditions assayed in the Parkin-knockout mice. The Xiong et al. study offers an entry point for explorations of the role of Pink1, Parkin, and DJ-1 in the cytoplasm. The priority now becomes identifying in vivo contexts in which this complex functions.

The targeting of tumors is made possible through establishing protein signatures specific for each cancer type. The recent recognition of the higher expression levels of HSP90 and its accumulation in tumor cell mitochondria has made the HSP90 network a feasible target for neutralization. HSP90 antagonizes the mitochondrial permeability transition, blocking cytochrome c release and apoptosis. In this issue of the JCI, Kang et al. report the synthesis of Gamitrinsibs, which target mitochondrially localized HSP90, specifically killing human cancer cell lines, and provide a fresh approach for cancer treatment (see the related article beginning on page 454).

The speed of accumulation of experimental data about normal as well as cancer cells has increased exponentially in the last several decades. Presently, our arsenal of knowledge is equipped with detailed information about cell proliferation, differentiation, and cell death induction pathways and the myriad of intricate interactions among them. Abnormalities in tumor suppressor genes and oncogenes have been correlated with disease states, and all of these tremendous advances have resulted in the heightened expectation that novel and better cancer therapies are clearly within reach. Yet, the most frequently applied treatment strategies continue to rely on “old school” therapies, combining surgery, chemotherapy, and/or radiotherapy. Chemotherapy and radiotherapy target proliferating cells, which include the rapidly dividing tumor cells but do not exclude normally proliferating cells of the skin and gastrointestinal tract. The generally low efficiency of cures for advanced cancers, the severe side effects of current therapy regimens, and the risk of posttherapeutic relapse have all contributed to the current and ongoing rush to find novel alternative therapeutic approaches (1).

New generation of anticancer drugs
Ideally, 21st century, clever, anticancer drugs are expected to target tumor cells specifically and spare damage to normal tissues. Thus, the search for tumor-specific markers or signatures has become the major focus of genomics, proteomics, and systems biology studies (2). It has been easier to find the signatures of certain types of cancers; for example, the human ERBB2/neu (HER2/neu) protein is overexpressed in 30% of breast cancer patients (3) and the identification of this marker has made possible the generation of a neutralizing HER2/neu monoclonal antibody (known as Herceptin or trastuzumab), currently used successfully in the clinic (4). Trastuzumab is a breakthrough in the fight against cancer and provides the impetus for other researchers in their studies.

Another molecular signature, the overexpression of antiapoptotic BCL2 family members in human leukemias (5, 6), melanoma (7), and hepatocellular carcinoma (8), was used to generate a distinct class of molecular drugs. In this case, the BH3 domain of proapoptotic BCL2 family members or synthetic drugs mimicking the BH3 domain were used to neutralize the apoptosis-blocking action of BCLXL, BCLW, and/or BCL2 (9, 10). The aim was to tip the balance of expression of antiapoptotic/proapoptotic BCL2 family members in order to induce cell death. The most successful BH3 mimetic in phase III trials is ABT-737, which is currently used to treat primary chronic lymphocytic leukemia (11, 12).

The mechanism of action of the drugs discussed above is based on targeting singular protein products, and the success of these drugs is exceptional considering the many thousands of compounds that have been tested in clinical trials and have failed. Drug designers have now begun to focus on identifying drugs that target signaling pathways, rather than singular proteins. Yet, another aspect of pathway-oriented drug discovery concerns the compartmental distribution of the components of the pathway at hand. The targeting of nodal signaling proteins localized in specific subcellular organelles, without affecting the expression or activities of these proteins in other cellular compartments, opens a new window for designing more effective anticancer drugs.

HSP90 network activity in tumor cell mitochondria
In this issue of the JCI, Kang et al. provide evidence of the successful utilization of a quite recently identified tumor signature, the mitochondrial accumulation of HSP90-network proteins, for apoptosis induction (13). Using Western blot analysis, mitochondrial HSP90 was previously found to be constitutively expressed at high levels in cervical carcinoma (HeLa), breast cancer (MCF-7), colon cancer (HCT-116), and B cell lymphoma (Raji) cell lines, suggesting that HSP90 may be critically important for tumor cell growth and/or survival (14). The same group of investigators had already shown via immunohistochemistry that mitochondria of tumor cells, but not most normal tissue samples, contain HSP90 and its related molecule TNF receptor-associated protein 1 (TRAP-1) (14). HSP90 and TRAP-1 were determined to interact with cyclophilin D (CYPD) and block its ability to cause mitochondrial outer membrane permeabilization, which is considered to be responsible for engaging the apoptotic cascade in numerous cell death pathways (Figure 1) (14, 15).

Normally, HSPs are upregulated upon establishment of stressful conditions, such as hyperthermia, oxidative damage, lack of nutrients, and others, and their main function is to serve as chaperones and catalyze the proper folding of certain client proteins (16). HSPs have been shown to regulate apoptosis signaling pathways at several steps. For example, HSP70 binds to the apoptosome component APAF1 and negatively regulates the
