Asthma is considered a Th2 cell–associated disorder. Despite this, both the Th1 cell–associated cytokine IFN-γ and airway neutrophilia have been implicated in severe asthma. To investigate the relative contributions of different immune system components to the pathogenesis of asthma, we previously developed a model that exhibits several features of severe asthma in humans, including airway neutrophilia and increased lung IFN-γ. In the present studies, we tested the hypothesis that IFN-γ regulates mast cell function in our model of chronic asthma. Engraftment of mast cell–deficient KitWsh/Wsh mice, which develop markedly attenuated features of disease, with wild-type mast cells restored disease pathology in this model of chronic asthma. However, disease pathology was not fully restored by engraftment with either IFN-γ receptor 1–null (Ifngr1−/−) or Fcε receptor 1γ−null (Fcer1g−/−) mast cells. Additional analysis, including gene array studies, showed that mast cell expression of IFN-γR contributed to the development of many FcεRIγ-dependent and some FcεRIγ-independent features of disease in our model, including airway hyperresponsiveness, neutrophilic and eosinophilic inflammation, airway remodeling, and lung expression of several cytokines, chemokines, and markers of an alternatively activated macrophage response. These findings identify a previously unsuspected IFN-γ/mast cell axis in the pathology of chronic allergic inflammation of the airways in mice.

**Introduction**

Asthma is a complex disorder characterized by chronic inflammation of the airways, airway hyperresponsiveness (AHR), airflow obstruction, and airway wall remodeling (1, 2). Many features of asthma are thought to reflect consequences of Th2-dominated immune responses to allergens in which Th2-type cytokines such as IL-4 and IL-13, and the Th2-associated immunoglobulin IgE, contribute to intricate pathways that result in inflammation and tissue damage (3). Mast cells are considered critical for the development of asthma phenotypes because of their ability to release, upon activation by IgE and specific antigen, a diverse range of autacoid mediators, chemokines, cytokines, and growth factors (4). Infiltration of the airway with eosinophils is also thought to be important in the pathology of asthma (1–4).

However, studies of patients with well-characterized asthma have suggested that neutrophils, in addition to eosinophils, may have important roles in asthma (5). Patients with chronic severe or acute fatal asthma exhibit increased numbers of airway neutrophils (6–9), and neutrophilic inflammation is positively correlated with the severity of airflow obstruction (10, 11). Moreover, airway neutrophilia and eosinophilia are not mutually exclusive (10, 12). Patients with severe asthma, compared with those with mild or moderate asthma, have both a greater percentage of sputum neutrophils and evidence for higher continuing release of eosinophil-derived mediators (13).

Other evidence suggests a possible role for the Th1 cell–associated cytokine INF-γ, as well as Th2 cell–associated cytokines, in some asthmatic subjects. Leukocytes in the BAL fluid from asthma patients can produce IFN-γ ex vivo (14), and, compared with moderate asthmatics, patients with severe asthma exhibit increased numbers of sputum neutrophils and eosinophils, increased epithelial or subepithelial expression of IFN-γ or IL-8, and decreased subepithelial expression of IL-4 (15). Increased lung levels of IFN-γ (16) or other evidence for the involvement of this cytokine (17–23) have been reported in some mouse models of allergic inflammation of the airways, but such studies have indicated that Th1 responses (17–19, 23) or IFN-γ (20–22) may have effects that contradict (18–20), enhance (17, 21, 23), or prolong (22) features of Th2 responses in these settings.

While the different results in various studies regarding the potential roles of IFN-γ in allergic airway inflammation may reflect, at least in part, differences in the mouse models and/or experimental approaches that were employed, taken together this prior work indicates that Th2- and Th1-associated pathways can interact in such settings (16, 17, 23, 24). There are many potential sources of IFN-γ during airway inflammation, including activated CD4+ Th1 cells, CD8+ T cells, and NK cells, as well as γδT cells, macrophages, dendritic cells, NKT cells, naive CD4+ T cells, and B cells (25–27). Whatever its cellular source, IFN-γ can exert pleiotropic effects through a receptor complex (IFN-γ receptor [IFN-γR]) composed of two chains: IFN-γR1 (also known as IFN-γR0), the major ligand-binding subunit, and IFN-γR2 (also known as IFN-γRβ), which is required for IFN-γ signal transduction and for increasing the affinity of IFN-γR1 to its ligand (25, 28).

We developed a mouse model of chronic allergic inflammation of the airways that exhibits several features of chronic asthma in humans, including inflammatory responses in the lungs that include both neutrophils and eosinophils (29). Most features of this model were markedly attenuated or absent in genetically mast cell–deficient mice, and optimal development of many of these “mast cell–dependent” characteristics required mast cell expression of Fcε receptor 1γ (FcεRIγ), which is necessary for mast cell activation via FcεRI-bound IgE and specific antigen or by immune
After OVA challenge, whereas with the peak of responsiveness occurring between 3 and 9 hours and have no significant effect on antigen-stimulated histamine release in rat intestinal mast cells (34). While these in vitro studies suggest that the effects of INF-γ on mast cell activation may vary according to species and/or anatomic site, the importance of INF-γ in regulating mast cell function in vivo has not been investigated. However, given the evidence that INF-γ can influence mast cell function in vitro, we were intrigued by the idea that INF-γ might regulate mast cell function in our model of chronic allergic inflammation of the Airways.

In the present study, we tested this hypothesis by evaluating the effects of INF-γ on mast cell function in vitro and by comparing features of our chronic asthma model in WT, Ifng−/−, and Ifngr1−/− mice and in genetically mast cell–deficient KIt−/− mice grafted with WT, Ifng−/−, or FcerIg−/− mast cells.

**Results**

INF-γ and INF-γR contribute to this model of chronic allergic inflammation. We first evaluated whether INF-γ or INF-γR contributes to airway responsiveness to antigen or airway inflammation in this model (29). As expected (29), WT mice exhibited a significant increase in enhanced pause (Penh, a measure of airway resistance in unrestrained, non-anesthetized mice) after antigen challenge, with the peak of responsiveness occurring between 3 and 9 hours after OVA challenge, whereas Ifng−/− or Ifngr1−/− mice exhibited significantly attenuated Penh responses to OVA challenge (Figure 1A). OVA-sensitized Ifng−/− and Ifngr1−/− mice also exhibited significantly decreased numbers of total BAL fluid leukocytes after OVA challenge, as well as significant reductions in individual types of leukocytes, including monocytes, macrophages, neutrophils, eosinophils, and lymphocytes (Figure 1B). We also found that, in WT C57BL/6 mice, i.p. treatment with a single dose of 5 μg INF-γ, given 30 minutes before or 3 hours after the last of 9 intranasal (i.n.) challenges with OVA, significantly increased both the Penh response to that OVA challenge and the number of neutrophils in the BAL fluid 24 hours after OVA challenge (Supplemental Figure 1; supplemental material available online with this article; doi:10.1172/JCI43598DS1). By contrast, treatment with a neutralizing antibody to INF-γ (100 μg per mouse, i.p., at 3 hours after the ninth OVA challenge), compared with treatment with an isotype-matched control antibody, significantly reduced both the Penh response to that OVA challenge and the number of neutrophils, eosinophils, and lymphocytes in the BAL fluid 24 hours after OVA challenge (Supplemental Figure 1). Taken together, these results support the conclusion that INF-γ and the INF-γR can significantly enhance these features of the model, but do not clarify which INF-γR–bearing cell type(s) contributed to these effects.

INF-γ can increase mast cell production of histamine and cytokines in vitro. Because many features of this model require mast cells and mast cell expression of the FcεRI chain for full development (29), we next evaluated whether INF-γ can influence mast cell activation via FcεRI. Bone marrow–derived cultured mast cells (BMMC MCs) generated in vitro from WT, INF-γR1–deficient, or FcεRI–deficient mice were sensitized overnight with an anti-dinitrophenol–specific (anti-DNP–specific) monoclonal mouse IgE and then challenged for 1 hour or 24 hours with various concentrations of specific antigen (DNP-HSA) with or without INF-γ at 1 or 5 ng/ml. Activation of mast cells with IgE+Ag resulted in the dose-dependent secretion of histamine, IL-6, and IL-13 by WT or IfngR1−/− BMCMCs (Figure 2), but no detectable release of IL-4, INF-γ, or the chemokines CXCL1, CXCL2, CCL9, CCL11, CCL12, or CCL24. INF-γ significantly increased the release of histamine, IL-6, and IL-13 by IgE+Ag-stimulated WT BMCMCs, whereas treatment of the cells with INF-γ alone was without effect (Figure 2 and Supplemental Figure 2). FcεRI–deficient BMCMCs were not detectably respon-

![Figure 1](http://www.jci.org)
sive to IgE+Ag challenge, with or without IFN-γ (Figure 2). The ability of IFN-γ to enhance dose-dependently the IgE+Ag-induced mast cell production of IL-13 is of particular interest (Supplementary Figure 2), since IL-13 is thought to contribute to the development of asthma through such effects as promoting subepithelial fibrosis (in part by upregulating synthesis of arginase-1), increasing mucus secretion, and eliciting AHR (35).

Lung expression of IFN-γ. To assess the importance of mast cell signaling via IFN-γR versus FcεRIγ in vivo, we compared features of our model in 5 groups of age-matched mice, all of them on the C57BL/6 background: WT mice, genetically mast cell–deficient Kit\(^{W-sh/W-sh}\) mice, and Kit\(^{W-sh/W-sh}\) mice engrafted with mast cells derived from WT, IFN-γR1–deficient, or FcεRIγ–deficient mice. Compared with PBS treatment in control groups, OVA sensitization and challenge resulted in significant increases in the amounts of IFN-γ in the lungs of each of the 5 types of mice tested (including the profoundly mast cell–deficient Kit\(^{W-sh/W-sh}\) mice) (Figure 3A).

By contrast, none of the groups of OVA-sensitized mice exhibited levels of lung IL-4 after OVA challenge that differed significantly from those in the corresponding PBS-treated groups (Figure 3B). OVA-sensitized and -challenged mice also exhibited elevations in lung levels of IL-17, a cytokine that has been implicated in the development of neutrophilic infiltrates in several settings (36); however, all groups of OVA-challenged mice developed similar elevations in lung levels of IL-17 (Supplemental Figure 3).

Mast cell IFN-γR can increase airway responses to antigen or methacholine. OVA-treated WT mice or Kit\(^{W-sh/W-sh}\) mice engrafted with WT mast cells (WT BMCMCs → Kit\(^{W-sh/W-sh}\) mice) exhibited significantly increased Penh responses to methacholine (a measure of AHR) or to antigen, while little or no enhancement of Penh responses to methacholine or antigen occurred in identically sensitized and challenged mast cell–deficient Kit\(^{W-sh/W-sh}\) mice or in Kit\(^{W-sh/W-sh}\) mice engrafted with Ifngr1\(^{−/−}\) or Fcer1g\(^{−/−}\) mast cells (Ifngr1\(^{−/−}\) BMCMCs → Kit\(^{W-sh/W-sh}\) or Fcer1g\(^{−/−}\) BMCMCs → Kit\(^{W-sh/W-sh}\) mice) (Figure 4, A and B, and Supplemental Figure 4, A and B). Similar results were obtained when we measured the effects of methacholine challenge on lung resistance (R\(_L\)) and dynamic compliance (C\(_{dyn}\)) in anesthetized, tracheostomized mice (Figure 4, C and D, and Figure 3).
critical mast-cell-dependent effects in this model primarily are those that influence end-organ tissue manifestations of antigen challenge in sensitized mice, rather than any potential mast-cell-dependent effects on sensitization to antigen and/or the generation of antigen-specific IgE or IgG antibodies.

* Mast cell IFN-γR can increase airway inflammation. Histologic analysis (Figure 5, A–E, K, and L) and examination of BAL fluids (Figure 5N) confirmed that mast cells are required for optimal development of antigen-induced lung inflammation in this model (29) and showed, unexpectedly, that such leukocyte infiltration was markedly and significantly reduced in mice in which only mast cells lacked IFN-γR, as well as in those in which only mast cells lacked FcεR1. Baseline numbers of mast cells/mm² of peribronchial tissue were similar in all groups of PBS-treated control mice except KitW-sh/W-sh mice, which totally lacked mast cells (Figure 5, F–J and M). We did not detect differences in the anatomical distribution of the 3 different types of mast cells (i.e., WT, Ifngr1−/−, and FcεR1−/−) that had been adoptively transferred into the KitW-sh/W-sh mice, either in PBS-treated or OVA sensitized and challenged mice. However, as has been reported for mast cell–engrafted WBB6F1–KitW-sh/W-sh (37) and C57BL/6–KitW-sh/W-sh (38, 39) mice, KitW-sh/W-sh mice containing adoptively transferred mast cells exhibited more mast cells in the periphery of the lungs than did WT mice. OVA treatment significantly increased the number of peribronchial mast cells in WT BMCMCs→KitW-sh/W-sh and Ifngr1−/− BMCMCs→KitW-sh/W-sh mice, but not in FcεR1−/− mice (Figure 5, F–J and M). These findings confirmed that mast cells must express FcεR1 in order to undergo significant expansion in this model (29) and show that this antigen-induced increase in mast cell numbers does not require that the mast cell be able to respond to IFN-γ via IFN-γR.

* Mast cell IFN-γR can increase airway remodeling. We confirmed that mast cells are required for the full development of features of antigen-induced airway remodeling in this model (29), including subepithelial fibrosis (Figure 6, A–C), increases in lung collagen (Figure 6F), and hyperplasia of mucus-secreting goblet cells (Figure 6G), and that mast cell expression of FcεR1 contributed more substantially to the development of increased lung collagen than to goblet cell hyperplasia in this model (Figure 6, F and G, and ref. 29). Moreover, mice in which only mast cells lacked IFN-γR exhibited impairment in the antigen-induced development of increased levels of subepithelial fibrosis (Figure 6, A–E), lung collagen (Figure 6F), and airway goblet cells (Figure 6G) that were very similar to those observed in mice in which only mast cells lacked FcεR1.

Mast cell expression of each receptor also was required for optimal antigen-induced and mast cell–dependent increases in lung lev-

Els of tissue inhibitor of metalloproteinases–1 (TIMP-1) and integrin α7 (Figure 6, H and I). TIMP-1, a major inhibitor of MMP-9, is thought to contribute to a profibrotic environment and airway remodeling by reducing extracellular matrix turnover (40). Integrin α7 is thought to regulate smooth muscle cell proliferation and is required for the expression of a contractile phenotype by human airway myocytes (41, 42). In mice in which mast cells lacked either FcεRI or IFN-γR, we observed only minimal (albeit statistically significant) antigen-induced increases in TIMP-1 (Figure 6H). By contrast, the development of antigen-dependent increases in lung levels of integrin α7 appeared to be virtually entirely dependent on mast cell expression of IFN-γR, whereas this effect was still evident, although at a significantly (~32%) reduced level, in mice whose mast cells lacked FcεRI (Figure 6I).

Mast cell IFN-γR is required for optimal expression of lung chemokines. C-X-C chemokines, including CXCL1 and CXCL2, are predominantly chemotactic for neutrophils, whereas chemokines with C-C motifs are chemotactic for monocytes, macrophages, dendritic cells, lymphocytes, NK cells, eosinophils, and basophils (43). Using a microarray-based analysis of lung gene expression as a screening tool (GEO GSE27066), we found that OVA sensitization and challenge induced markedly increased lung levels of mRNA for CXCL1, CXCL2, CCL11, CCL12, and CCL24 in WT mice and in WT BMCMCs → KitW-sh/W-sh mice, but not in mast cell–deficient KitW-sh/W-sh mice; we then confirmed these findings by measuring lung levels of the corresponding proteins (Supplemental Figure 6). Levels of these chemokines in OVA-treated mice whose mast cells lacked either IFN-γR or FcεRI were very similar to those in mast cell–deficient KitW-sh/W-sh mice (there was a minimal, but statistically significant, OVA-induced increase in lung levels of CXCL1 in Ifngr1−/− BMCMCs → KitW-sh/W-sh mice) (Supplemental Figure 6A). OVA treatment induced an increase in lung CCL9 levels...
that was largely, but not entirely, mast cell dependent, and the mast cell–dependent increase in levels of CCL9 in antigen-treated mice required mast cell expression of both IFN-γ and FcεRIγ (Supplemental Figure 6C).

These findings show that mast cells greatly increase lung levels of several chemokines in this model, including those that are chemotactic for neutrophils, eosinophils, monocytes, and lymphocytes, cells whose numbers in the lungs are regulated in a largely mast cell–dependent manner (Figure 5, A–C, K, L, and N). Moreover, mast cell transfer studies indicated that the ability of mast cells to enhance lung levels of these chemokines in Kit<sup>W-sh/W-sh</sup> mice was virtually ablated if the adoptively transferred mast cells lacked either IFN-γR or FcεRIγ (Supplemental Figure 6). By contrast, antigen-dependent changes in lung levels of IL-17 occurred independently of mast cells (Supplemental Figure 3).

**Inflammatory cytokines and markers of an alternatively activated macrophage response.** IFN-γ can increase IgE+Ag-dependent production of IL-6 and IL-13 by mast cells in vitro through effects mediated by IFN-γR (Figure 2). Consistent with these findings, OVA treatment significantly enhanced lung expression of IL-6 and IL-13 in WT or WT BMCMS→Kit<sup>W-sh/W-sh</sup> mice but not in mast cell–deficient Kit<sup>W-sh/W-sh</sup> mice or in Kit<sup>W-sh/W-sh</sup> mice containing mast cells that lacked either IFN-γR or FcεRIγ (Figure 7, A and B). Our microarray-based screen for increased gene expression identified both IL-33 and markers of an alternatively activated macrophage response as substantially upregulated in this model in OVA-sensitized and challenged WT mice. IL-33 is a member of the IL-1 family that is produced mainly by fibroblasts, epithelial cells, and endothelial cells (44). The receptor for IL-33 is composed of two units, the orphan receptor ST2 and IL-1 receptor accessory protein (IL-1RACP) (44). IL-33 can amplify both Th1 and Th2 responses (44) and can directly induce cytokine production by mast cells (including IL-13 production; ref. 45) or basophils, as well as enhance IgE+Ag-dependent activation of these cells (44–46). In the presence of IL-13, IL-33 also can promote polarization of alveolar macrophages toward an alternatively activated macrophage phenotype in vitro or in vivo (47). OVA sensitization and challenge markedly increased lung levels of IL-33 in a manner that was largely, but not entirely, mast cell dependent, and the mast cell–dependent component of this response required that mast cells express both IFN-γR and FcεRIγ (Figure 7C).

Th2 responses, including those associated with models of airway allergic inflammation, are often associated with the development of an alternatively activated macrophage response (48). Such responses, which contribute to the mitigation or resolution of the pathology associated with allergic inflammation (48), can include increased lung expression of the macrophage receptor with collagen...
From the IFNgamma (via IFN-gamma) and mast cell expression of IFN-gamma (by mast cells) is required to effect mast cell–dependent increases in MARCO in antigen-challenged mice (Figure 7D). By contrast, mast cell signaling via both IFN-gamma and mast cell–dependent increases in lung levels of each of these proteins (Figure 7, A–C). Taken together, these findings are consistent with the hypothesis that elevations of lung levels of IFN-gamma are mechanistically upstream of mast cells in this model and that colostrum of mast cells with IFN-gamma significantly enhanced their ability to release histamine, IL-6, and IL-13 in response to activation with IgE and specific antigen (Figure 2), and IFN-gamma dose-dependently enhanced the IgE+Agr dependent release of IL-6 and IL-13 by mast cells in concentrations as low as 0.1 ng/ml (Supplemental Figure 2). In vivo, the significant increases in lung levels of IL-6, IL-13, and IL-33 in this model occurred by wholly (for IL-6 and IL-13) or largely (for IL-33) mast cell–dependent mechanisms (Figure 7, A–C). Moreover, such mast cell–dependent elevations in lung levels of these cytokines required that mast cells express both FceR1A and IFN-gamma (Figure 7, A–C). Taken together, these findings are consistent with the hypothesis that elevations of lung levels of IFN-gamma are mechanistically upstream of mast cells in this model and that mast cells, mast cells are the only cells that genetically lack IFN-gamma R. The poor development of many important features of this model in such mice therefore demonstrates that these features require functions of IFN-gamma R–responsive mast cells that cannot be provided adequately by any of the other IFN-gamma –responsive cell types present in this setting.

Most of the other features of the model that we analyzed — including striking mast cell–dependent increases in airway responses to antigen or airway hyperreactivity to methacholine (Figure 4), tissue neutrophils and eosinophils (Figure 5, K and L, respectively) — require mast cell expression of both FceR1A and IFN-gamma R. The poor development of many important features of this model in such mice therefore demonstrates that these features require functions of IFN-gamma R–responsive mast cells that cannot be provided adequately by any of the other IFN-gamma –responsive cell types present in this setting.

**Discussion**

Our findings reveal an important and previously unsuspected role for IFN-gamma–dependent activation of mast cells in the development of the inflammation and tissue pathology associated with this mouse model of chronic allergic inflammation of the airways. As summarized in Supplemental Table 1, mast cell expression of IFN-gamma R is required for optimal development of many features of this model, including AHR to methacholine, inflammation of the airways (with infiltrates containing many neutrophils and eosinophils), airway remodeling (i.e., increases in both numbers of epithelial goblet cells and lung collagen), and markedly increased lung expression of several cytokines, chemokines, and markers of an alternatively activated macrophage response. It bears emphasis that in KitW-sh/W-sh mice engrafted with Ifngr1−/− mast cells, mast cells are the only cells that genetically lack IFN-gamma R.

# Levels of inflammatory cytokines and other molecules in the lung

Levels of IL-6 (A), IL-13 (B), IL-33 (C), MARCO (D), and arginase-1 protein (E) and the relative levels of Saa3 mRNA (F) were measured in the lungs 24 hours after the ninth OVA or PBS challenge in WT C57BL/6 (Kit−/−), mast cell–deficient C57BL/6→KitW-sh/W-sh (Kit−/−), C57BL/6 (WT) BMCMCs→C57BL/6→KitW-sh/W-sh, Ifngr1−/− BMCMCs→C57BL/6→KitW-sh/W-sh, and Fcer1g−/− BMCMCs→C57BL/6→KitW-sh/W-sh mice and the corresponding PBS-treated control mice. White bars: PBS-treated groups; black bars: OVA-sensitized and -challenged groups. **P < 0.01, ***P < 0.001 versus the corresponding PBS controls; †††P < 0.001 versus group indicated. n = 6–10 per group. EU, experimental units, with the arbitrary value of 100 EU assigned to the values for the MARCO (D) or arginase-1 (E) content in the lung protein extract of 4 randomly selected WT C57BL/6 mice in the OVA-sensitized and -challenged group.

respectively) and BAL fluid leukocytes (Figure 5), and lung levels of a panel of chemokines (Supplemental Figure 6) — were affected equally (and, in general, markedly diminished) by a lack of either mast cell IFN-γR or mast cell FcεRIγ (Supplemental Table 1). These results indicate that signaling via both IFN-γR and FcεRIγ is required for mast cells to perform the functions important for the development of these mast cell–dependent features of the model. However, some of the in vivo effects of mast cell activation via IFN-γR or FcεRIγ are distinct. The increase in lung mast cells in this model is critically dependent on mast cell FcεRIγ, as revealed both in this (Figure SM) and in our prior study (29), but this expansion of lung mast cells occurs independently of mast cell IFN-γR (Figure SM). Because mast cells that lack FcεRIγ exhibit ablation of signaling through FcεRIγ and, as a consequence of that, are significantly impaired in their ability to expand in numbers in the lungs in this model of chronic allergic inflammation, changes in the pathology that are affected by the lack of mast cell expression of FcεRIγ might reflect the lack of FcεRIγ–dependent signaling in those mast cells that are present in such animals, the reduced numbers of lung mast cells in these mice, or both.

Regarding features of lung remodeling, mast cells lacking either IFN-γR or FcεRIγ were equally and markedly impaired in their ability to increase levels of lung collagen (Figure 6F) and TIMP-1 protein (Figure 6H). Because the marked mast cell–dependent increase in lung levels of integrin αv protein in this model was completely ablated if mast cells lacked IFN-γR but only modestly, albeit significantly, reduced if mast cells lacked FcεRIγ (Figure 6I). Similarly, the marked and apparently entirely mast cell–dependent increase in lung levels of MARCO protein in this model required that mast cells express IFN-γR but not FcεRIγ (Figure 7D). By contrast, two other markers of an alternatively activated macrophage response, substantially increased lung levels of arginase-1 protein and Saa3 mRNA, were also induced in a largely or entirely mast cell–dependent manner, but in this case the effect was either ablated (in the case of arginase-1 protein; Figure 7E) or markedly reduced (in the case of Saa3 mRNA; Figure 7F) if mast cells lacked either IFN-γR or FcεRIγ. Finally, our data indicate that one important feature of the model, the development of large numbers of intraepithelial goblet cells, is entirely mast cell dependent but that this function can be largely sustained by mast cells lacking either IFN-γR or FcεRIγ (Figure 6G).

Our results support the conclusion that optimal expression of many critical mast cell functions in this model requires costimulation of the cells via both IFN-γ/IFN-γR and FcεRIγ, whereas other mast cell functions can be influenced by each receptor independently of the other. We do not know why costimulation of mast cells with IFN-γ is important for the development of so many, but not all, of the features of this model of chronic allergic inflammation. Nor can our mast cell engraftment approach permit one to determine whether particular “mast cell–dependent” features of the model reflect direct actions of mast cells (such as effects of mast cell–derived mediators on leukocytes or structural cells) or indirect effects (such as those mediated by other cells of innate or acquired immunity that are recruited to, and/or influenced in, the lungs in a mast cell–dependent manner). However, our study clearly establishes that mast cell responsiveness to IFN-γ, a cytokine classically regarded as a marker of a Th1 response, is as critical for the development of many features of the inflammation, tissue remodeling, and airflow functional changes observed in this model of chronic allergic inflammation of the airways as is mast cell expression of FcεRIγ. Moreover, in our in vitro findings show that even low concentrations of IFN-γ can enhance IgE-Ag-dependent release of cytokines by mast cells (Figure 2 and Supplemental Figure 2), suggesting that this mechanism may influence IgE-dependent mast cell functions in many settings, not just those associated with marked elevations of IFN-γ.

Others have shown that various populations of rodent and human mast cells can express IFN-γR or respond to IFN-γ in vitro (31–34), but the importance of mast cell expression of IFN-γR in vivo was not clear. The unexpected identification of an IFN-γ/mast cell axis in this mouse model of airway allergic inflammation challenges the notion that the mast cell’s function in this and perhaps other models of chronic allergic inflammation is entirely or predominantly under the control of the Th2 cell response. Moreover, treatment with a single injection of a neutralizing antibody to IFN-γ, administered to mice 3 hours after the last OVA challenge, reduced the magnitude of both the Penh response and the increases in BAL fluid leukocytes induced by antigen challenge (Supplemental Figure 1), findings indicating that IFN-γ represents a therapeutic target in this mouse model.

Are these findings relevant to human asthma? One always must be cautious in attempting to extrapolate findings from any animal model of a disease to its human counterpart, and the relevance of our observations in mice to asthma in humans remains to be determined. For example, while it is well established that the phenotypic features of mast cells can vary based on species, anatomical site, and exposure to cytokines and other factors in the cells’ microenvironments (57, 58), little is known about the regulation of the surface expression of IFN-γR by mast cells, whether in the airways or in any other site. Moreover, the relationship of our mouse model of chronic allergic inflammation of the airways to particular clinical subsets of human asthma is not clear. However, as a first step toward addressing the relationship of our mouse model to human asthma, we used gene set enrichment analysis (GSEA) (59) to compare the set of genes that Laprise et al. (60) reported were upregulated in the bronchial biopsy specimens from 4 allergic asthmatic subjects with mild asthma (compared with those from 4 control subjects without asthma) and those genes that were upregulated in our mouse model in OVA-sensitized and -challenged (vs. PBS-treated control) mice. We detected significant (i.e., P < 0.05) similarity between genes upregulated in the human asthma specimens compared with those upregulated in our model in WT mice (P = 0.021) or WT mast cell–engrafted Kitw/wAv/wAv mice (P = 0.020), but not in identically sensitized and challenged mast cell–deficient Kitw/wAv/wAv mice or in Kitw/wAv/wAv mice engrafted with Ifngr1−/− or Fcεr1−/− mast cells (Supplemental Figures 7–12 and Supplemental Tables 2 and 3). While these findings are intriguing, it will be of interest to repeat such GSEA studies using data sets derived from additional subsets of asthma subjects, including those with increased numbers of airway neutrophils and/or increased levels of IFN-γ in the lung, when data of this type become available. Such work, together with other studies in human subjects, will be important in the attempt to decide whether IFN-γ merits investigation as a therapeutic target for reducing the pathology characteristic of IgE–associated allergic inflammation in asthma and perhaps other settings.

Methods

Mice. C57BL/6 WT, Ifngr−/−, and Ifngr1−/− mice were originally purchased from The Jackson Laboratory. C57BL/6-Kifng−/−/− mice were provided by Peter Besmer (Molecular Biology Program, Memorial Sloan-Kettering Cancer Center, New York, New York, USA); these mice were then backcrossed to C57BL/6J for more than 10 generations. All of the C57BL/6 WT mice and C57BL/6-
Kit<sup>W-sh/W-sh</sup> mice used in the experiments reported herein were bred and raised in the same room in the Stanford Laboratory Animal Facility. FcerIγ<sup>−/−</sup> mice on the C57BL/6 background (B6.129P2-Fcrt1gmR1avN12) were purchased from Taconic. Age-matched female mice were used for all experiments. All animal care and experimentation reported herein were conducted in compliance with the guidelines of the NIH and with the specific approval of the Institutional Animal Care and Use Committee of Stanford University.

**Mast cell engraftment.** Engraftment of mast cells in mast cell–deficient C57BL/6 or C57BL/6-Lifgr1<sup>−/−</sup>, or C57BL/6-FcerIγ<sup>−/−</sup> mice were cultured in WEHI–3–conditioned medium (ATCC TIB-68), as a source of IL-3, for 4–5 weeks to generate cell populations that contained more than 99% immature mast cells (BMCMCs). BMCMCs (5 × 10<sup>5</sup>) were injected into each mouse via the tail vein, and the recipients (e.g., WT BMCMCs→Kit<sup>W-sh/W-sh</sup>, Lifgr1<sup>−/−</sup> BMCMCs→Kit<sup>W-sh/W-sh</sup>, or FcerIγ<sup>−/−</sup> BMCMCs→Kit<sup>W-sh/W-sh</sup>) mice were used for experiments 18 weeks later.

**Production of histamine, cytokines, and chemokines by mast cells in vitro.** BMCMCs were described as above and in ref. 29 from femoral bone marrow cells of C57BL/6 WT, Lifgr1<sup>−/−</sup>, or FcerIγ<sup>−/−</sup> mice and were sensitized with 1 μg/ml H1-ez2 anti-DNP IgE at 37°C overnight. After IgE sensitization, BMCMCs were suspended in DMEM medium (MediaTech) supplemented with 10% heat-inactivated FCS (Sigma-Aldrich), 50 μg/ml streptomycin (Invitrogen), and 50 U/ml penicillin (Invitrogen) at a final concentration of 5 × 10<sup>5</sup> cells/ml. For activation of the BMCMCs, antigen (DNP-HSA; Sigma-Aldrich) was added to the BMCMC culture supernatants, and the results were expressed as percent histamine release (64). ELISA kits for total plasma IgE and IgG<sub>1</sub> were purchased from Bethyl Laboratories; the ELISA kit for OVA-specific IgE was purchased from MB Biosciences. Concentrations of OVA-specific IgG<sub>1</sub> in the plasma were measured by direct ELISA (29).

**Chemokines:** Chemokines in the BMCMC culture supernatants were measured using an Enzyme Immunoassay Kit (Beckman Coulter) according to the manufacturer’s instructions and the results were expressed as percent histamine release (64). ELISA kits for CXCL1, CXCL2, CCL9, CCL11, CCL12, CCL24, IL-33, and TIP-1 were purchased from R&amp;D Systems; ELISA kits for IL-4, IL-6, IL-17, IFN-γ were purchased from eBioscience. We used direct ELISA methods to measure levels of MARCO, integrin α7, and arginase-1. Primary antibodies against MARCO or integrin α7 were purchased form R&amp;D Systems, and primary antibodies against arginase-1 were purchased from Novus Biologicals.

**Measurement of protein and collagen.** The protein levels of tissue samples were measured using a BCA Protein Assay Kit form Thermo Scientific. Tissue collagen levels were measured using a Sircol Soluble Collagen Assay Kit from Biocolor Life Science Assays.

**Quantitative RT-PCR.** Total RNA isolated from the left lungs using TRIzol Reagent (Invitrogen) was reverse transcribed using the High-Capacity cDNA Archive Kit (Applied Biosystems) according to the manufacturer’s instructions. Quantitative real-time PCR was performed using the ABI 7500 Real-Time PCR System (Applied Biosystems) with the following cycling parameters: 10 minutes at 95°C, then 40 biphasic cycles of 15 seconds at 95°C, and 1 minute at 60°C. Primers and probes for SAA3 were purchased from Applied Biosystems.

**Statistics.** Unless otherwise specified, differences in airway response between groups were tested for statistical significance using ANOVA. The unpaired Student’s t test (2 tailed) was used for all other analyses. A P value less than 0.05 was considered statistically significant. Unless otherwise specified, all data are presented as mean ± SEM or mean ± SEM.

**Acknowledgments**

We thank C. Liu and E. Zuo for excellent technical assistance; P. Besmer (Sloan-Kettering Institute) for the gift of C57BL/6-Kit<sup>W-sh/W-sh</sup> mice; Fu-Tong Liu (University of California, Davis) for the gift of monoclonal IgE to DNP generated from ascites induced by the hybridoma cell line H1-DNP-e-26; Lester Kohzik (Harvard School of Public Health) for discussions regarding lung expression.
of MARCO; Sally E. Wenzel and Silvana Balzar (University of Pittsburgh School of Medicine) for helpful discussions regarding IFN-γ in human asthma; and members of the Galli laboratory for discussions. This study was supported by grants from the NIH: AI70813, AI23990, CA72074 (to S.J. Galli), and LM009719 (to A.J. Butte).
