Acute kidney injury (AKI) often results from ischemia reperfusion, sepsis, or exposure to nephrotoxins and is associated with a high rate of mortality and morbidity. Advances in understanding the pathophysiology of AKI may lead to the development of specific therapies. Although there is evidence of an important role for immune cells in AKI, the specific relevant populations and the mechanisms of their actions are unclear. In this issue of the JCI, Li et al. demonstrate that adenosine manipulates DC responses to kidney injury, raising hope that immunotherapy could be a tangible approach to AKI.

Immune cells in acute kidney injury
Acute kidney injury (AKI) occurs in 3%–7% of patients admitted to tertiary care hospitals in industrialized nations (1). In native kidneys, AKI-associated mortality approaches 50% when occurring in the intensive care unit, and AKI in allograft kidneys worsens short- and long-term kidney function. Ischemia/reperfusion injury (IRI) is a common cause, as are sepsis and nephrotoxins. There is no specific therapy except for supportive care and dialysis. While much of the initial work on AKI pathophysiology focused on the highly abundant epithelial cell, more recent studies have revealed an important role for immune, endothelial, and peritubular resident cells (2). The evidence for the role of immune cells emerged from studies showing that leukocyte adhesion molecules (LAMs) mediated AKI; however, many of the beneficial effects were independent of neutrophils being targeted by LAMs, which was initially confusing (3–5). Further studies demonstrated that T cells were activated during AKI, migrating to kidney, and directly mediated tissue injury (6). This opened up the possibility of other immune populations such as DCs and NKT cells participating in AKI (ref. 7 and Figure 1). Work in other organs, such as lung, liver, and brain, has also revealed the engagement and participation of traditional immune cells in alloantigen-independent acute tissue injury (2, 8).

Adenosine receptor 2A agonist-induced tolerogenic DCs in AKI
Adenosine, a breakdown product of ATP/ADP metabolism that accumulates in AKI, has been known to regulate lymphocyte responses and is thus an attractive target for modulating immune cells and improving outcomes in AKI (9). In the current issue of JCI, Li et al. have elegantly demonstrated that DCs can be modulated by adenosine or selective adenosine receptor agonists to improve the course of AKI when administered prior to or at the time of ischemic injury (10). Li et al. found that kidney dysfunction and inflammation after IRI were accentuated in mice deficient in the adenosine receptor A2AR only on CD11c+ DCs, while selective A2AR agonist ATL313 administration led to tissue protection. Studying bone marrow-derived DCs primed with the glycolipid antigen α-galactosylceramide (αGC) to activate NKT cells led to a worsening of kidney dysfunction after mild (26 minutes) ischemia. Treating DCs that were primed with the NKT agonist αGC with adenosine receptor agonist protected from AKI. The DC therapy was effective if given 2 or 7 days prior to ischemic injury, or at 1 or 6 hours after injury, but not when started 24 hours after IRI. This finding indicates that modified DC cell therapy could be applied for prevention and early treatment; however, most patients are diagnosed well after ischemic injury, so the lack of effect when given 24 hours after ischemia may limit its practical application.

A key mechanism by which adenosine-mediated DC cell therapy works in AKI appears to be via IL-10, a powerful anti-inflammatory cytokine. IL-10 increased in kidney after adenosine-stimulated DC therapy, and blocking endogenous IL-10 reversed the protective effect. Furthermore, administering adenosine-stimulated DC therapy to IL-10–deficient mice led to a loss of the protective effect of the DCs, clearly implicating IL-10 as a protective mechanism (10). This finding is in line with previous reports showing that IL-10 is an important protective cytokine in AKI (11).

The promise of immune cell therapy for acute kidney injury

Acute kidney injury (AKI) often results from ischemia reperfusion, sepsis, or exposure to nephrotoxins and is associated with a high rate of mortality and morbidity. Advances in understanding the pathophysiology of AKI may lead to the development of specific therapies. Although there is evidence of an important role for immune cells in AKI, the specific relevant populations and the mechanisms of their actions are unclear. In this issue of the JCI, Li et al. demonstrate that adenosine manipulates DC responses to kidney injury, raising hope that immunotherapy could be a tangible approach to AKI.
more, what are the early signals that engage DCs in AKI as well as activate the other related immune pathways? Since T cells are known to modulate outcomes in AKI, either in a deleterious or protective way, depending on their functional subtype (20), a key question is what the initial stimulus is for such a rapid response in the absence of alloantigen. To date, no AKI antigen has been identified as driving immune responses. One of the confusing findings has been that many different resident renal immune cells, T and B cell, DC, NK and NKT cell, macrophage, and neutrophil crosstalk accentuates the postischemic inflammation. These cells produce and respond to cytokines, chemokines, oxygen free radicals, complement, coagulant factors, and other mediators. Adenosine, acting via A2AR, activates DCs, which in turn modulate NKT cell function by decreasing IFN-γ secretion. This triggers increased IL-10 levels, which subsequently downregulate postischemic inflammation. Panels depict the outer medulla. Adapted with permission from the Journal of Molecular Medicine (2).

Unanswered questions

The current study by Li et al. sheds light on exciting mechanistic pathways during ischemic AKI and stimulates many other questions. The location of the effect of the adenosine-stimulated DCs could be intrarenal or extrarenal, including in lymph nodes. The recognition of IL-10 as a key mediator of these effects raises the question of the identity of the cell producing IL-10, since it is probably not the DCs themselves. Are all of the effects due to IL-10, and if so, could IL-10 be infused at an appropriate dose and time in the place of cell therapy? Further, what are the early signals that engage DCs in AKI as well as activate the other related immune pathways? Since T cells are known to modulate outcomes in AKI, either in a deleterious or protective way, depending on their functional subtype (20), a key question is what the initial stimulus is for such a rapid response in the absence of alloantigen. To date, no AKI antigen has been identified as driving immune responses. One of the confusing findings has been that many different immune cells are known to mediate AKI, but their relationships with each other, their redundancies, and molecular mecha-
Glucocorticoids are a powerful tool used to treat a range of human illnesses, including autoimmune diseases and cancer, and to prevent rejection following organ transplantation. While lifesaving for many, they come with a steep price, often leading to obesity, insulin resistance, diabetes, and osteoporosis. In this issue of the JCI, Brennan-Speranza and colleagues provide evidence that the osteoblast-derived peptide osteocalcin is one of the drivers of the metabolic derangements associated with glucocorticoid therapy. This novel mechanism could open up new avenues for the treatment of these disorders.
