CEREBRAL HEMODYNAMICS DURING CEREBRAL ISCHEMIA
INDUCED BY ACUTE HYPOTENSION

By Frank A. Finnerty, Jr., Lloyd Witkin, and Joseph F. Fazekas with
the technical assistance of Marie Langbart and William K. Young

town and George Washington Medical Divisions, District of Columbia General
Hospital, Washington, D. C.)

(Submitted for publication February 1, 1954; accepted May 20, 1954)

The extreme dependence of the brain upon its
circulation for substrates essential for the main-
tenance of its metabolic activity is well recognized.
A cessation of the cerebral circulation for only a
few minutes, as occurs in cardiac arrest, results in
irreversible brain damage. The brain, for the most
part, is an aerobic organ and its large oxygen de-
mands probably account for its unusual suscepti-
bility to circulatory disturbances.

The oxygen consumed by the normal adult brain
(3.5 cc. per 100 Gm. per min.) is extracted from
approximately 800 cc. of blood passing through it
each minute. The minimum blood flow require-
ments of the brain, i.e., the rate at which signs of
cerebral ischemia become manifest, have not been
accurately determined. Previous efforts to esti-
mate the critical rate have been made both in ani-
mals (1) and in man (2) but the procedures utilized
for the determination of cerebral blood flow were
not sufficiently quantitative to warrant defi-
nite conclusions.

In order to study this problem, cerebral hem-
dynamic and metabolic changes were determined
before and during acute reductions in arterial pres-
sure induced by drug administration and/or
postural adjustments.

MATERIALS AND METHOD

Forty-four patients were studied. The subjects in
whom hypotension was drug-induced were separated into
the following four groups so that the influence of age
and hypertension on the susceptibility of the brain to
cerebral ischemia could be determined: Group 1, seven
normotensive subjects under 50 years of age; Group 2,
ten normotensive subjects over 60 years of age; Group 3,
eight patients with essential hypertension; and Group 4,

The mean arterial blood pressure (MAP) was obtained directly from the femoral artery by means of a damped aneroid manometer (6) and also by the usual auscultatory method. Since the subjects were tilted, it was necessary to correct for the hydrostatic pressure differences between the femoral and carotid arteries. This pressure differential was equal to the vertical height between the two arteries which varied somewhat in individual studies. The mean arterial pressures, presented in the tables are the calculated mean carotid pressures. This correction, as well as the fact that the subjects were resting in a tilted position for approximately thirty minutes, probably accounts for the normotensive values in some of the subjects with essential hypertension (Table 1C).

Electrocardiograms were taken before, during, and after the experimental procedure in 21 subjects, and the internal jugular venous pressures were recorded before and during the study in 14 subjects. The internal jugular venous pressures were measured by means of a spinal fluid manometer; the zero point was considered to be the needle level.

RESULTS

An analysis of the results obtained in the 37 subjects in whom the mean arterial pressure was reduced to levels at which signs of cerebral ischemia became manifest discloses the following: The mean arterial pressure fell from a mean value of 109 mm. Hg to 48 mm. Hg (p < .01). The rate of cerebral blood flow decreased significantly from a mean of 51 to 31.5 cc./100 Gm./min. (p < .01). The mean cerebral vascular resistance also fell significantly from 2.2 to 1.5 (p < .01). The mean cerebral arteriovenous oxygen difference increased significantly from 5.80 volumes per cent to 9.20 volumes per cent (p < .01). Despite definite signs of cerebral ischemia, the cerebral oxygen utilization did not change appreciably from control values during the experimental flow. The CO₂ content of the arterial and cerebral venous blood did not change significantly with a reduction of the mean arterial pressure. Similarly there were no significant changes in the blood pH in eleven of the subjects studied.

Tables I, A through E, present the results of the individual groups. Table II presents data on seven subjects in whom the mean arterial pressure was not lowered sufficiently to induce signs of cerebral ischemia.

Though considerable variation is seen in the level of arterial pressure at which signs of cerebral ischemia became manifest, ranging from mean values of 89 mm. Hg in the malignant hypertensive group to 29 mm. Hg in the normotensive group over 60 years of age, the value for the cerebral blood flow is not appreciably different in the individual groups studied (Tables I, A through E). The mean value for cerebral blood flow in the group of subjects in whom cerebral ischemia was not induced (Table II) is significantly higher than in any of the other groups.

† Significant difference, p < .01.
‡ Significant difference, p < .05.
The mean cerebral vascular resistance fell significantly in both the young and elderly normotensive subjects (Table IA and IB) and subjects with essential hypertension (Table IC). The cerebral metabolic rate did not change significantly from the control values in any of the individual groups. In all groups presented, the cerebral arteriovenous oxygen difference was significantly increased.

In the 14 subjects studied, the internal jugular venous pressure decreased from 83 to 47 mm. of water with an average decrease of 36. Since this represents a difference of approximately 3 mm. Hg, it would only change the cerebral vascular resistance by 0.1 units.

Of interest was the complete lack of clinical and electrocardiographic evidence of coronary insufficiency in these acute studies, particularly in the elderly subjects, many of whom had abnormal electrocardiograms. The control electrocardiograms in 15 subjects were abnormal—two subjects showed evidence of old posterior myocardial infarction, the rest showed non-specific myocardial changes. When symptoms of cerebral ischemia developed, the average heart rate was 64 per minute, a reduction of 35 per cent.

DISCUSSION

Cerebral blood flow and arterial pressure

It is evident from these studies that despite the subject's age, original level of arterial pressure, per cent reduction of arterial pressure, or original rate of cerebral blood flow, signs of cerebral ischemia developed when the mean cerebral blood flow was reduced to 31.5 cc. per min. per 100 Gm. of brain. The mean values of the experimental cerebral blood flows for the individual groups varied between 29 and 35 cc. per 100 Gm. of brain per min. The fact that in the group without cerebral ischemia (Table II) the subjects were alert despite a mean cerebral blood flow of 43.9 indicates that the critical rate of cerebral blood flow is below this value. Apparently significant reductions in cerebral blood flow from normal are possible without inducing manifestations of cerebral ischemia.

The degree of fall in arterial pressure required to produce cerebral ischemia, as might be anticipated, was related to the cerebral vascular resistance. When the cerebral vascular resistance could be significantly reduced (all groups except the postural hypotensive group and the malignant hypertensive group), the arterial pressure could be lowered markedly before signs of cerebral ischemia became manifest. When the vascular resistance could not be significantly reduced, the level of arterial pressure at which cerebral ischemia developed was higher. Only in situations where the vascular resistance remains fixed, can there be a direct relationship between per cent reduction in cerebral blood flow and mean arterial pressure. Since the mean arterial pressure at which signs of cerebral ischemia developed varied considerably (89 to 29 mm. Hg), it is evident that a critical level of arterial pressure as such does not exist.

Cerebral vascular resistance

The initial values for the cerebral vascular resistance in the individual groups varied. The finding of an increased cerebral vascular resistance in the hypertensive subjects confirms the results of Kety and others (7-10). The highest mean value for the cerebral vascular resistance was noted in the malignant hypertension group. While the increased cerebral vascular resistance in the essential hypertension group was significantly reduced with hypotension, the cerebral vascular resistance in the malignant hypertension group remained relatively fixed. It may be that the inability to overcome this increased cerebral vascular tone accounted for the development of signs of cerebral ischemia at normal levels of arterial pressure.

It was particularly interesting that the elderly normotensive subjects showed a significant reduction in cerebral vascular resistance when their mean arterial pressures were reduced. This confirms previous observations demonstrating considerable alterations in the vascular tone of elderly subjects (11, 12). In the group studied, the cerebral vascular resistance was not as high as we expected it might be. In a preliminary study (13) on elderly hypertensive subjects with a markedly elevated cerebral vascular resistance, signs of cerebral ischemia have occurred at normotensive levels. An overall decrease in cerebral vascular resistance in normotensive and hypertensive subjects with cerebral arteriosclerosis should not be taken to mean that all cerebral vessels are capable of under-
going the same degree of relaxation. It is possible that with an acute drop in blood pressure, circulation through the more rigid cerebral vessels may be seriously impaired. This may explain why transient episodes of cerebral ischemia may sometimes be associated with a relatively slight decrease of the mean arterial pressure. The explanation for the decrease in cerebral vascular resistance attendant with the reduction in mean arterial pressure is not apparent from these studies since there was no change in either pH or CO₂ content.

**Cerebral metabolic rate**

Even though signs and symptoms of cerebral ischemia were present in most of the subjects studied, there was no significant change in cerebral oxygen utilization between the control and induced hypotension studies. There can be no question that in these acute experiments the manifestations of cerebral ischemia were most likely due to a decreased oxygen delivery to certain cerebral cells since there was neither hypoglycemia nor any obvious impairment of cerebral enzymatic activity. It is suggested from the neurological signs evoked that not all regions of the brain were equally affected by the cerebral ischemia. The variable sensitivity of the different areas of the brain to reduced oxygen tensions and to depressant drugs is well recognized. It may be that with a reduction of the rate of cerebral blood flow those areas with the highest metabolic requirements are first affected. The failure to observe significant changes in cerebral oxygen utilization in these studies may be due to the fact that the method employed is not sufficiently sensitive to reflect changes in the metabolic activity of a relatively small number of cerebral cells. In this regard it should be mentioned that during sleep (14) and with light Pentothal® anesthesia (15) one does not observe significant changes in cerebral oxygen utilization with this procedure.

**Cardiovascular effects**

The fact that small doses of hexamethonium were given (average dose was 8 mg. of the ion) and the frequent finding of bradycardia and increased perspiration in the drug-induced studies suggests that full blocking doses of the drug were not given, and the effects observed were not entirely drug-induced. The hypotensive effect of small doses of the ganglionic blocking agent enhanced by tilting apparently activated vasovagal reflexes which accounted for the bradycardia observed. With the onset of collapse, cardiac output and right ventricular pressures decreased sharply (16). These latter observations are consistent with the concept that the mechanism of cerebral ischemia was due to loss of peripheral vasoconstrictor tone which in our tilted subjects promoted failure of venous return and hence of cardiac output.

**SUMMARY AND CONCLUSIONS**

1. The effect of cerebral ischemia induced by the intravenous administration of hexamethonium and/or tilting on cerebral hemodynamics and metabolism was determined in young and elderly normotensive subjects and in subjects with essential and malignant hypertension. Seven subjects with postural hypotension were also studied.

2. In all subjects, signs and symptoms of cerebral ischemia developed when the cerebral blood flow was reduced to 31.5 cc. per 100 Gm. of brain per min. (mean value).

3. The degree of fall in mean arterial pressure which resulted in cerebral ischemia varied from 29 to 80 mm. Hg.

4. Subjects with a relatively fixed cerebral vascular resistance (malignant hypertension) developed cerebral ischemia at higher mean arterial pressures.

5. Although blood pressures were lowered to levels resulting in clinical signs and symptoms of cerebral ischemia, no change in the over-all cerebral oxygen consumption was noted.

6. The development of clinical signs of cerebral insufficiency without simultaneous clinical or laboratory evidence of coronary insufficiency suggests that the brain may be more sensitive to acute hypotension than is the heart.
