Pemphigus vulgaris is an autoimmune blistering disease that is induced by binding of antibodies to a 130/85-kD protein complex on epidermal keratinocytes. An in vivo experimental model of this disease was developed by reconstituting severe combined immunodeficiency (SCID) mice with 1-10 x 10^7 PBL from patients with naturally occurring pemphigus vulgaris. Of 49 reconstituted mice, 34 (69%) produced human IgG levels of > 0.1 mg/ml. Circulating anti-pemphigus antibodies were found in 20 of the 34 successfully reconstituted mice; 44% of these animals had deposits of human IgG in their own skin after it was traumatized by either heat or cold. Spontaneous pemphigus vulgaris-like blisters associated with human IgG deposits were rarely found in mouse skin. By contrast, allogeneic human skin grafted to 10 to 12 mice before reconstitution with patients' PBL developed pemphigus vulgaris-like lesions containing human IgG deposits. These results demonstrate that SCID mice can serve as a model of an antibody-mediated human autoimmune skin disease.
Development of Pemphigus Vulgaris-like Lesions in Severe Combined Immunodeficiency Disease Mice Reconstituted with Lymphocytes from Patients

Abstract

Pemphigus vulgaris is an autoimmune blistering disease that is induced by binding of antibodies to a 130/85-kD protein complex on epidermal keratinocytes. An in vivo experimental model of this disease was developed by reconstituting severe combined immunodeficiency (SCID) mice with 1-10 x 10^7 PBL from patients with naturally occurring pemphigus vulgaris. Of 49 reconstituted mice, 34 (69%) produced human IgG levels of > 0.1 mg/ml. Circulating anti-pemphigus antibodies were found in 20 of the 34 successfully reconstituted mice; 44% of these animals had deposits of human IgG in their own skin after it was traumatized by either heat or cold. Spontaneous pemphigus vulgaris-like blisters associated with human IgG deposits were rarely found in mouse skin. By contrast, allogeneic human skin grafted to 10 of 12 mice before reconstitution with patients’ PBL developed pemphigus vulgaris-like lesions containing human IgG deposits. These results demonstrate that SCID mice can serve as a model of an antibody-mediated human autoimmune skin disease. (J. Clin. Invest. 1993. 92:2401–2407.) Key words: skin autoimmune disease • animal model • antibodies • pemphigus

Introduction

Pemphigus vulgaris (PV) is an autoimmune disease of skin and mucous membranes. Because of severe and extensive blistering, the disease can be fatal if untreated. It is mediated by antibodies to an epithelial-specific, intercellular antigen found in the suprabasal epidermis and mucosal epithelial layer. The PV antigen is a 130-kD glycoprotein (1) which is disulfide-linked to the 85-kD placoglin (2). cDNA cloning has recently identified the PV antigen as a member of the cadherin family of Ca^2+-dependent cell adhesion molecules (3). Blister formation after antibody binding to the PV antigen might be related to antibody inhibition of cadherin interactions (4) and may involve activation of the complement cascade (5) and/or plasminogen activators (6).

Current experimental animal models for studies on the pathogenesis of PV are based on the passive transfer of patients’ Ig to newborn mice (7) or of patients’ sera to athymic nude mice grafted with human oral mucosa (8). In the mucosal graft model, the incidence of epithelial cell detachment is low (3 of 25 grafts). Newborn mice injected with IgG fractions from pemphigus patients develop cutaneous blisters within 1 to 3 d. The lesions disappear after discontinuation of IgG injections and repeated injections of adult mice with patients’ Ig are without a pathogenic effect.

The availability of severe combined immunodeficiency (SCID) mice, which lack both functional B and T lymphocytes (9, 10), makes continuous production of human Ig in the murine host possible. In SCID mice grafted with human fetal liver and thymus cells (11) or PBL (12), the human cells home to lymphatic organs, thus reconstituting elements of the human immune system. Production of human Ig is seen after 2 to 4 wk and remains detectable over 20 wk after engraftment. Lymphocytes from patients with autoimmune diseases such as systemic lupus erythematosus and biliary cirrhosis can be expanded in the murine host to reproduce the human disease (13, 14).

Lymphocytes from patients with pemphigus produce autoantibodies against epidermal and mucosal antigens (15). Because the human antibodies also bind to antigens on mouse keratinocytes (1, 16), we investigated the effect of continuous antibody exposure on keratinocytes on the development of PV-like disease in adult mice. Although SCID mice reconstituted with PBL from patients with PV rarely developed blisters in skin or mucous membranes, reconstituted mice that were previously grafted with full-thickness human skin developed PV-like blisters in the human grafts. Thus, SCID mice can provide an in vivo model for human pemphigus.

Methods

Reconstitution of SCID mice with human PBL. C.B.-17 SCID (scid/ scid) mice were bred at The Wistar Institute Animal Facility. At 6 wk of age, mice were tested for endogenous Ig production and only fully immunodeficient mice were used for experiments. PBL were obtained with informed consent from patients with PV or healthy adult volunteers by centrifugation of heparinized blood on Ficoll-Hypaque gradients (Pharmacia LKB, Piscataway, NJ). PBL in RPMI 1640 medium were administered intraperitoneally either immediately after separation or after 2-36-wk storage in liquid nitrogen. The viability of injected cells was > 90%. The number of PBL injected varied initially between 1 and 10 x 10^7/mouse; it was subsequently adjusted to 2.5-3.0 x 10^7/mouse. SCID mice within one group received equal numbers of lymphocytes from the same donor. Mice reconstituted with PBL from healthy volunteers and mice injected intravenously with 30 mg of human gammaglobulins prepared from healthy individuals (ICN Biomedicals Inc., Lisle, IL) served as controls. All animals were housed under pathogen-free conditions in microisolator cages and observed daily or at a minimum three times per wk.

Detection of human Ig. Total human IgG in plasma of reconsti-
tuted SCID mice was measured by enzyme-linked immunosorbent assays in 96-well microtiter plates (Falcon Pro-bind; Becton Dickinson & Co., Lincoln Park, NJ) coated with 5 μg/ml of goat IgG anti-human IgG (Sigma Chemical Co., St. Louis, MO). After overnight blockade with 1% BSA and subsequent washings, serial dilutions of mouse plasma were added, followed by peroxidase-conjugated goat IgG anti-human IgG (γ-chain-specific; Sigma Chemical Co.). Antibody binding was visualized with the ABTS peroxidase substrate system (Kirkegaard-Perry, Gaithersburg, MD) and quantitated by comparison with a purified human IgG control preparation (Cappel Laboratories/Or ganon Teknika, Durham, NC).

Circulating PV antibodies in the plasma of reconstituted SCID mice were detected by indirect immunofluorescence assays on frozen sections of esophagus from African Green monkeys. For comparison of various substrates, air-dried sections of monkey esophagus, human skin, and murine skin were incubated with serial dilutions (1:10 to 1:320) of plasma from PV patients for 30 min, washed in PBS, pH 7.3, for 10 min, and further incubated for 30 min with FITC-labeled goat IgG anti-human IgG. Slides were then covered with Fluoromount-G mounting medium (Fisher Scientific, Philadelphia, PA) and sealed. Sections were evaluated in a Leitz fluorescence microscope equipped with epi-illumination (Leitz USA, Deerfield, IL). PV antibodies in the epidermis stain in a typical cobblestone cell membrane pattern specific for this disease, allowing the routine clinical use of this assay for diagnosis.

For detection of human IgG in skin and mucous membranes by direct immunofluorescence, tissues were snap-frozen in OCT compound. Sections (5 μm) were air-dried for 1 h, fixed in 95% ethanol, and incubated for 30 min with FITC-conjugated goat IgG anti-human IgG. Slides were then washed and mounted. Portions of tissues (liver, lungs, spleen, pancreas, kidney, and lymph nodes) were fixed in 10% buffered formaldehyde for histopathological examinations. Sections (4 μm) were stained with hematoxylin and eosin and analyzed under an Ortholux universal microscope (Leitz USA).

To facilitate human Ig deposition, dorsolateral skin of anesthetized mice was traumatized 8 wk after reconstitution with PBL. A metal spatula immersed in liquid N₂ was applied onto different sectors of the skin for 2, 5, and 15 s, respectively, in a 5-cm² area previously treated with Zip Wax depository (Lee Pharma, El Monte, CA). A spatula, heated in water to 60°C, was then applied in three different sectors of the skin for 15, 30, and 60 s, respectively. Mice were sacrificed 24 h later and biopsies were obtained for histological and immunofluorescence assays.

Immunoprecipitation of PV antibodies in antibodies in human and mouse plasma was done as described (1) using the squamous cell carcinoma cell line SCaBER (17) and normal human keratinocytes as antigen source. Briefly, confluent monolayer cells were detached with 100 mM Versene ( Gibco BRL, Gaithersburg, MD), washed with PBS, and labeled for 1 h with 0.1 mg/ml NHS-LC-Biotin (Pierce Chemicals, Rockford, IL), followed by lysis with RIPA buffer (1% sodium deoxycholate, 1% Triton X-100, and 0.1% SDS) containing 0.05 mM PMSF (Sigma Chemical Co.). The solubilized material was centrifuged at 36,000 g for 10 min at 4°C and the supernatant was dialyzed against 0.3% NP-40. Aliquots of plasma samples of reconstituted SCID mice and control plasma or sera of patients with PV were incubated with 100 μl protein G Sepharose for 1 h at 4°C and washed three times with RIPA buffer. Overnight incubation of the cell lysate with the Sepharose-antibody complexes was followed by vigorous washing in RIPA buffer. The prepared material was then run on a 10% polyacrylamide gel containing 1% SDS (18). Bands were visualized by avidin-conjugated alkaline phosphatase and 5-bromo, 4-chloro, 3-indolylphosphate/nitroblue tetrazolium (Sigma Chemical Co.) as substrate.

Transplantation of human skin to SCID mice. Six- to 8-wk-old SCID mice received transplants of full-thickness human skin. A circular graft bed ~ 1.5 cm in diameter was prepared in the depilated lateral abdominal region. Mouse skin down to the fascia was then removed with curved scissors and human skin from either neonatal foreskin or adult human breast (discarded skin from reduction mammoplasty) were placed onto the wound bed and held in place with 5-0 monofilament sutures (Dermalon; Davis & Geck Inc., Danbury, CT). The transplantation site was then covered with a Band-Aid™ and clipped

![Figure 1. Production of human Ig in SCID mice reconstituted with PBL from patients with PV. Plasma levels of human IgG 4, 6, and 8 wk after reconstitution are given for individual mice without (●) or with (+) evidence of lymphoma upon necropsy.](image-url)
dorsally and ventrally to the mouse skin using surgical staples (Auto-
clip; Clay Adams, Parsippany, NJ). A layer of Micropore surgical tape
(3M Co., St. Paul, MN) was then applied. Grafted mice were housed in
individual cages. After 4 wk, grafts had healed and mice were reconsti-
tuted with PBL from patients with PV. If blisters appeared after reconsti-
tution, mice were sacrificed and skin grafts with the surrounding
murine skin were removed for histological examination. Parts of the
grafts were snap-frozen in OCT, fixed in 10% buffered formaldehyde,
and embedded in paraffin. Skin-grafted control mice that received
PBL from healthy donors and that had not developed blisters were killed
5 wk after administration of PBL for histological examination of skin
grafts.

**Results**

*Presence of human Ig in reconstituted SCID mice.* SCID mice
reconstituted with PBL from 12 patients with PV and 4 healthy
donors contained circulating human IgG. 4 to 8 wk after reconsti-
tution with 1–10 \( \times 10^7 \) PBL/mouse, 34 out of 49 mice
(69%) had human IgG levels of at least 0.1 mg/ml, with a
mean of 12.27 mg/ml (Table I, Fig. 1). The mean IgG levels
were higher if mice were reconstituted with 5–10 \( \times 10^7 \) PBL/
mouse than with 1–2.5 \( \times 10^7 \) PBL/mouse (16.6 mg/ml vs.
7.94 mg/ml, respectively). Human IgG was detected as early
as 3 wk after reconstitution and, in individual mice tested, for
at least 24 wk. Mice with IgG levels of 10 mg/ml or more often
subsequently developed abdominal lymphomas (Fig. 1). 5 out
of 37 mice (13.5%) reconstituted with 1–2.5 \( \times 10^7 \) PBL and 5
out of 12 mice (41.6%) reconstituted with 5–10 \( \times 10^7 \) PBL had
clinically or histologically confirmed lymphomas. Focal hep-
ic infiltration (19) was seen in 5 out of 37 mice (13.5%) injected
with 1–2.5 \( \times 10^7 \) and 8 out of 12 (66%) mice injected
with 5 \( \times 10^7 \) PBL (data not shown). Due to the higher inci-

Immunoprecipitation of the PV antigen from SCaBER cells with plasma from a SCID mouse reconstituted with PBL from a PV patient (PV SCID), plasma of PV patient (PV pt), or plasma from SCID mouse reconstituted with PBL from a healthy volunteer (control SCID). PV antigen is at 130-kD (arrow) and coprecipitates with the 85-kD placoglobin (arrowhead).

dence of lymphomas with time after reconstitution, mice were killed after 8 wk and the number of PBL was restricted to 2.5–3.0 × 10⁷/mouse.

Presence of anti–PV antibodies in SCID mice. 20 of the 34 mice (58%) that produced human IgG also had circulating antibodies with a PV-like binding pattern on tissue sections of monkey esophagus. The staining pattern in plasma from SCID mice reconstituted with PV patients’ PBL was similar to that of patients’ plasma (Fig. 2 A and B) whereas plasma from healthy donors or from mice reconstituted with PBL from normal donors did not stain tissue (Fig. 2 C and D) nor did plasma of mice injected with normal human IgG (not shown). The presence of anti–PV antibodies in the plasma of reconstituted mice was confirmed in immunoprecipitation experiments with epithelial cells as antigen source (Fig. 3). Antibodies in plasma of reconstituted mice and plasma/sera of PV patients bound the 130-kD PV antigen and co-precipitated the 85-kD placoglobin.

Spontaneous human IgG deposits in mouse skin associated with suprabasal acantholytic blister formation were occasionally observed (Fig. 4 A). Of the reconstituted mice in which the skin was traumatized by heat or cold (see protocol), 21 (44%) showed skin IgG deposits adjacent to the site of trauma (Fig. 4 B). By contrast, neither mice reconstituted with PBL from healthy donors (Fig. 4 C) nor those injected with human IgG (not shown) showed specific deposits in skin after traumatization.

Blistering disease in reconstituted SCID mice grafted with human skin. Human skin is the natural substrate for human anti–pemphigus antibodies in contrast to skin from adult mice. To determine whether human anti–pemphigus antibodies induce blister formation more readily in human than in mouse skin, 1.5 to 2 cm² full-thickness human skin grafts were applied to the lateral abdomen of SCID mice (Fig. 5 A); and 4 wk later, 16 mice were reconstituted with 2.5–3 × 10⁷ PBL from patients with PV or from normal donors (Table II). 16 to 33 d later, mice reconstituted with patients’ PBL developed lesions in the grafted human skin that varied from 3-mm erosions to denudation and crusting of the grafts (Fig. 5 B). Histologically, the skin adjacent to erosions showed intraepidermal cell dys- sion, with rounded acantholytic cells (Fig. 5 C). PV-like intercellular deposition of human IgG in the grafted human epidermis was found by direct immunofluorescence assays (Fig. 5 D and E). PBL from normal donors did not induce blistering lesions after injection into grafted SCID mice, and no epidermal IgG deposits were observed (not shown).

Discussion

SCID mice reconstituted with PBL from pemphigus patients had circulating anti–pemphigus antibodies. These antibodies rarely induced spontaneous blisters in mouse skin but consistently bound to epidermal keratinocytes after the skin was mildly traumatized by heat or cold. SCID mice first grafted with full-thickness human skin, which were then reconstituted with pemphigus patients’ PBL, consistently had human antibody deposits in the human grafts that were often associated with spontaneous blistering 18 to 33 d after reconstitution.

Although the staining pattern of human anti–pemphigus antibodies in mouse skin was similar to that in human skin, PV

antigen appears expressed in greater amounts on human than on mouse skin. Possibly, human antibodies recognize epitopes on the PV antigen that are masked or absent on the murine antigen. The human PV antigen has recently been identified as a member of the cadherin family (3); the degree of sequence homology to the mouse equivalent has not yet been established. Differences in protein sequence, glycosylation, or cell surface exposure of the PV antigen may further account for differences in antibody binding between human and mouse skin. Reconstitution of adult mice with pemphigus patients'

PBL rarely induced blisters in the mouse skin; passive administration of isolated IgG from pemphigus patients, results in blister formation in mouse skin only if newborn animals are injected with large Ig quantities of up to 1 g (7). On the other hand, adult mice first grafted with human skin and then reconstituted with patients' PBL spontaneously developed blisters in the grafts with a histological pattern that is the same as in the naturally occurring disease in patients. The human skin grafts retained their architecture, including a dermal vasculature, for several months after grafting, allowing penetration of antibodies through the basement membrane to the epidermis in the same way as in human skin. Human blood vessels anastomose with the murine vasculature at the graft bed and, upon stimulation by human tumor cells, human vessels in the skin grafts sprout into the expanding tumor mass (19).

SCID mice reconstituted with human PBL showed little evidence of graft-vs.-host disease and studies by others indicate varied reactions, ranging from lymphocytic infiltration around hepatic bile ducts (12, 13) to focal liver necrosis (20). We observed only focal infiltrates of CD45-positive cells in livers in 13 of 49 mice (data not shown). The observed variation of human IgG levels in reconstituted mice is consistent with previous studies (13, 21, 22). Mice with high IgG levels (> 15 mg/ml) often developed lymphomas, which are commonly found in SCID mice reconstituted with PBL from EBV-positive donors (23). The time course of EBV-induced lymphomas varies depending on the percentage of EBV-positive cells in the total lymphocyte population and the total injected dose (12). To delay lymphoma development, we restricted the number of injected PBL to 2–3 \( \times \) 10\(^7\) per mouse and completed the experiments 8 wk after reconstitution.

The routine screening of mice for “leakiness,” i.e., spontaneous IgM production, at 6 to 8 wk of age and the use of mice under the age of 12 wk helped prevent failures in reconstitution (24). Transplantation of human skin (25) in our laboratory was successful in 90% of more than 200 transplantations if the grafted human foreskin was used no later than 2 d after resection and if the adult skin showed no evidence of trauma from handling during surgery. We detected no obvious graft-vs.-graft reactions despite the use of allogeneic skin in these experiments in reconstituted mice. It remains to be determined whether any inflammatory reactions due to possible histoincompatibility of human PBL and skin contributes to blister development in this model. Autologous skin grafts from pemphigus patients were not done due to ethical considerations.

Models in experimental animals that closely mimic human antibody-mediated autoimmune diseases are rare. The animal model described here closely represents the naturally occurring disease because it involves both antibody-producing lymphocyte effector cells and epidermal keratinocytes (target cells) of human origin. Studies using this model can begin to address the questions that remain concerning the effector mechanisms of PV blister formation, the clonality of the antibody response in PV patients, and the identification of immunodominant epi-
topes on the PV antigen. The recent cloning of the PV antigen (3) should aid in epitope mapping efforts. The SCID model for PV should also be useful in developing new therapeutic approaches that go beyond the current symptomatic treatment with corticosteroids.

Acknowledgments

We thank Ms. T. Egner for help in animal experiments, Ms. E. Aglow and Ms. A. Radu for their assistance in histological studies, and Dr. J. Stanley for providing us with serum from a patient with PV for control to our immunoprecipitation experiments.
