Abstract

To determine whether β-adrenergic receptor agonist activation influences guanosine 5’-triphosphate–binding protein (G-protein) expression and β-adrenergic receptor kinase activity in the heart, we examined the effects of chronic β1-adrenergic receptor antagonist treatment (bisoprolol, 0.2 mg/kg per d i.v., 35 d) on components of the myocardial β-adrenergic receptor–G-protein–adenylyl cyclase pathway in porcine myocardium. Three novel alterations in cardiac adrenergic signaling associated with chronic reduction in β-adrenergic receptor agonist activation were found. First, there was coordinate downregulation of Giα2 and Gsα mRNA and protein expression in the left ventricle; reduced G-protein content was also found in the right atrium. Second, in the left ventricle, there was a twofold increase in β-adrenergic receptor–dependent stimulation of adenylyl cyclase and a persistent high affinity state of the β-adrenergic receptor. Finally, there was a reduction in left ventricular β-adrenergic receptor kinase activity, suggesting a previously unrecognized association between the degree of adrenergic activation and myocardial β-adrenergic receptor kinase expression. The heart appears to adapt in response to chronic β-adrenergic receptor antagonist administration in a manner that would be expected to offset reduced agonist stimulation. The mechanisms for achieving this extend beyond β-adrenergic receptor upregulation and include alterations in G-protein expression, β-adrenergic receptor–Gs interaction, and myocardial β-adrenergic receptor kinase activity. (J. Clin. Invest. 1995. 95:1271–1280.) Key words: adrenergic signaling • β-adrenergic receptor antagonist • heart failure • adenylyl cyclase

Introduction

β-Adrenergic receptor antagonists are used in the treatment of angina pectoris, hypertension, and heart failure. As agents that interfere with β-adrenergic receptor stimulation, it is reasonable to propose that these agents may affect the expression and interaction of myocardial signal-transducing elements in the β-adrenergic receptor–responsive adenylyl cyclase pathway. Clinical and experimental data suggest that chronic administration of β-adrenergic receptor antagonists affects cell surface β-adrenergic receptor number and physiological responsiveness in the heart (1). However, the mechanisms by which elements of the β-adrenergic receptor–adenylyl cyclase pathway are altered by such treatment and the nature of these alterations remain to be firmly established. Two elements that have received little previous attention but are likely to provide important insights into mechanisms for altered transmembrane signaling in the setting of reduced β-adrenergic receptor activation are myocardial guanosine 5’-triphosphate (GTP)γ-binding protein (G-protein) expression and β-adrenergic receptor kinase activity. G-proteins transduce signals from β-adrenergic receptors to effectors such as adenylyl cyclase and calcium channels, whereas β-adrenergic receptor kinase participates in receptor desensitization by catalyzing phosphorylation of agonist-occupied receptors (2).

Previous studies from our laboratory and others have shown that sustained β-adrenergic receptor activation can influence the expression of not only cell surface β-adrenergic receptors, but also Gs and Gi in the heart (3–20). Heart failure, a condition characterized in part by systemic neurohumoral adrenergic activation, is associated with reduced β-adrenergic receptor expression at mRNA and protein levels (4, 5, 15–17) and, in some studies, with alterations in the expression of cardiac G-proteins (4, 7, 8, 13, 18). Recent studies have shown that chronic isoproterenol infusion is associated with increased cardiac Giα2 content, possibly resulting from increased Giα2 mRNA transcription rates (11). Data from these studies, acquired from diverse pathophysiological models, provide evidence that G-proteins, similar to β-adrenergic receptors, are susceptible to regulation in the heart in a manner that may reflect adrenergic activation.

It was recently reported that β-adrenergic receptor kinase activity is increased in failing left ventricles obtained from humans with heart failure (17, 21). Based on these studies and others alluded to previously, we have asked whether signal-transducing elements such as G-proteins and β-adrenergic receptor kinase may be altered in a manner dependent upon the extent of β-adrenergic receptor agonist activation. We therefore treated pigs for 35 d with the β1-adrenergic receptor antagonist bisoprolol (22) to determine the effects of reduced β-adrenergic receptor activation upon cardiac G-protein expression and β-adrenergic receptor kinase activity. We tested the hypothesis that, in left ventricular myocardium, reduced β-adrenergic receptor agonist activation would be associated with altered expression of G-proteins and reduced β-adrenergic receptor kinase activity.

1. Abbreviations used in this paper: G-protein, guanosine 5’-triphosphate-binding protein; GST, glutathione S-transferase; ICYP, iodocyanopindolol.
Methods

Animals. 12 pigs (Sus scrofa), 50±8 kg (mean ±1 SEM) were used for the study. After acclimatization to human handling, animals received ketamine (50 mg/kg, i.m.) and atropine sulfate (0.1 mg/kg, i.m.) followed by sodium amytal (100 mg/kg, i.v.). Animals underwent endotracheal intubation, and halothane (0.5–1.5%) was delivered by a pressure-cycled ventilator for the duration of the surgical procedure. Left thoracotomy was performed and catheters were placed in the aorta and pulmonary artery. Six pigs were randomly selected to receive daily bisoprolol treatment. The remaining six pigs served as controls. The protocol was in accordance with the National Institutes of Health guidelines for the use of animals in research and was approved by the animal use committee at the Veteran’s Affairs Medical Center, San Diego, and the University of California, San Diego.

Bisoprolol treatment and heart rate responses. 2 wk after recovery from surgery, the six animals that were to receive bisoprolol underwent pharmacological testing to determine heart rate responsiveness. Two strategies were used. First, we measured basal heart rate 30 min after cholineric receptor blockade with glycopyrrolate (0.14 mg/kg, i.v.), a long-acting muscarinic cholineric antagonist. The dose of glycopyrrolate was selected from pilot studies; the absence of changes in heart rate in response to nitroglycerine-induced hypotension was used as a criterion for successful suppression of vagally mediated heart rate modulation. By removing the influence of acetylcholine on sinoatrial node phase 4 depolarization, heart rate should more directly reflect the influence of sinoatrial node β-adrenergic receptor responsiveness. We then administered bolus intravenous doses of isoproterenol until a maximal heart rate was achieved. After these studies were completed, animals received bisoprolol (0.2 mg/kg per d, i.v.) for the remainder of the study (35±2 d). The pharmacological tests were repeated 5–7 d after the initiation of treatment to document decreased heart rate responsiveness attributable to bisoprolol. Studies were then repeated just before the animals were killed. The detailed methodology can be found elsewhere (4, 23).

Terminal surgery. After 35±2 d, animals were anesthetized and intubated, and midline sternotomies were performed. The heart was removed and rinsed in sterile saline (4°C), and the coronary arteries were rapidly perfused with sterile saline (4°C). Right atrial samples were obtained from identical regions in all animals. Transmural samples of left ventricular free wall were taken midway from base to apex, near the midportion of the left anterior descending coronary artery. Myocardial samples were then frozen (−80°C). The time from heart removal to placing samples in liquid nitrogen was 5–10 min.

Membrane preparation. Frozen (−80°C) transmural samples were powdered in a stainless steel mortar and pestle (−80°C), placed in Tris buffer, and glass–glass homogenized. To assess adenylyl cyclase activity, the pellet of a 45,000-g centrifugation was resuspended in buffer and adenylyl cyclase studies were performed. For radioligand binding experiments, contractile proteins were extracted (0.5 M KCl, 20 min, 4°C) before the first centrifugation.

β-Adrenergic receptor binding studies. β-Adrenergic receptors were identified using the radioligand [3H]dihydropyridine (ICYP, 5–700 pM) in saturation isotherm experiments conducted on crude membrane preparations as previously described (4, 23). β1- and β2-adrenergic receptor numbers were determined in competition binding experiments using the selective β2-adrenergic receptor antagonist ICI 118,551 (10−10–10−4 M) as previously described (4). To evaluate adverse effects caused by retained bisoprolol, studies were repeated after multiple resuspensions and centrifugations (n=2); receptor quantification was unaffected. The affinity constants for ICYP and (−)-isoproterenol were similar in myocardium from control and bisoprolol-treated pigs, a result that strongly suggests the absence of bisoprolol in the membrane homogenates. Nevertheless, all membrane preparations for these experiments underwent a minimum of two centrifugations and resuspensions.

Determinations of the Ks for isoproterenol and the proportion of β-adrenergic receptors displaying high or low affinity binding (an assessment of the degree to which β-adrenergic receptors are coupled with Gs) were performed in competition binding experiments by incubating 100 pM ICYP with 10−10–10−4 M (−)isoproterenol with and without nonhydrolyzable GTP analogs (100 μM Gpp[NH]p or 100 μM guanosine 5′-O-(3-thiotriphosphate) [GTPγS]) as previously described (4).

Protein concentrations were determined by the method of Bradford (24). Previous experiments have established that β-receptors are not lost to the supernatant in our membrane preparations and that β-adrenergic receptor number is unaffected by thoracotomy alone (4, 14).

Adenylyl cyclase assays. Methods were modified from those of Salomon et al. (25) as previously described (4, 14). The following agents were used to stimulate cAMP production (final concentrations): (−)-isoproterenol (10 μM), GTP (100 μM) GTPγS (100 μM), AF (100 μM), and forskolin (100 μM). We found that cAMP production under these conditions was linear with respect to time and protein concentration and that 3-isobutyl-2-methylxanthine (1.0 mM), adenosine deaminase (5 U/ml), or both had no effect on basal or maximally stimulated cAMP production. Previous experiments established that adenylyl cyclase activity does not distribute to the supernatant of a 45,000-g centrifugation in our membrane preparation and that thoracotomy alone does not influence adenylyl cyclase activity (4).

Quantification of Gsα and Giα, by immunoblotting. Assay of αs and αt subunits of Gs and Giα, was conducted using standard SDS-PAGE and immunoblotting techniques (5, 20). Briefly, 100 μg of protein from each supernatant and resuspended pellet fraction of a 45,000-g centrifugation of crude myocardial homogenate derived from appropriate transmural samples was electrophoresed on a 10% denaturing gel for 4 h at 30 mA constant current. For quantification of cardiac α subunits, glutathione-S-transferase (GST; 25.6 kD)–Gsα subunit fusion protein expression vectors were constructed with pGEX-3X (Pharmacia LKB, Piscataway, NJ) and partial cDNA sequences that corresponded to the carboxyl terminus of the G-proteins (fragment 7, F7). These proteins were expressed in Escherichia coli strain NM522, and the resulting fusion proteins (GST–GsF7 and GST–GiF7; 31 kD and 30 kD, respectively) were purified, quantified (26), and used at four different dilutions per gel for standard curve generation. Low molecular weight standards were also included on each gel. Proteins were electroblotted onto nitrocellulose membranes (Amersham, UK) for 14 h at 70 V, 4°C (27). Transfer efficiency was recorded by photocopies of membranes dyed with reversible Ponceau staining, and gel retention was checked with Coomassie blue staining. Background blocking was accomplished by incubating membranes in Tris-buffered saline (TBS, pH 7.5) with 2% nonfat dry milk for 2 h at 25°C. Purified primary polyclonal antibodies (New England Nuclear, Boston MA; rabbit anti–G-proteins: RM/1 for Gαs; AS/7 for transducin, Gαs, and Gαt) were diluted 1:600 in 15 ml of TBS with 0.05% Tween 20 (TBS; pH 7.5) and 1% nonfat dry milk, and membranes were incubated for 14 h at 4°C (27). Autoradiographic detection of bands was performed by incubating membranes in 75 ml of TBS with 1% nonfat dry milk and 15 × 106 cpm 35S-labeled protein A (New England Nuclear) for 2 h at 25°C followed by thorough sequential washes in TBS, and placing against x-ray film (X-Omat AR, Eastman Kodak Co., Rochester, NY) for 5 d at −70°C. The 45- and 31-kD bands for Gαs and GST–GsF7 were removed from the membranes with background controls for gamma counting. Likewise, the 39- and 42.5-kD bands for Giαt and GST– GiαF7 were removed and counted. Using the specific activity of the GST fusion protein standards and the specific activity of the sample bands of interest, we calculated the tissue G-protein content. Gαs and Giα cDNAs were provided by Dr. A. Gilman (Texas Health Sciences Center, Dallas, TX) and Dr. Kaziro (Tokyo University, Japan). The fusion vector, pGEX-3X, was obtained from Pharmacia LKB.

RNA extraction. Total RNA was extracted from left ventricle and right atrium using a modification of the acid guanidinium thiocyanate–phenol–chloroform extraction method (28). Tissue samples were homogenized in 4.0 M guanidinium buffer, extracted twice with acidic phenol–chloroform, and precipitated with isopropanol. The final pellet was washed with 70% ethanol, dissolved in diethylpyrocarbonate-treated water, and stored at −80°C. The integrity and purity of the RNA were assessed by gel electrophoresis and the ultraviolet absorbance ratio
(260/280 nm); the sample was rejected if the ratio was <1.6 or if visual inspection of the gel photograph suggested degradation.

Construction of porcine riboprobes. CDNA was generated from total RNA isolated from porcine left ventricle through reverse transcription with oligo(dT) primers using in vitro transcriptions (Life Science Assoc., Bayport, NY). Partial fragments of porcine Gsa and Gic2 clones then were obtained through amplification of porcine cardiac cDNA pools via PCR. To ensure specificity, sense and antisense primers (vide infra) were designed to amplify specific regions of these clones where the sequences are highly diversified among different genes in the family.

The primers for the Gsa probe spanned a 455-nucleotide segment (908–1362) within exons 12 and 13 of the porcine gene. The primers for the Gic2 probe spanned a 154-nucleotide segment (247–400) within exons 3 and 4 of the porcine gene. Amplified clones were sequenced and compared with known sequences of the Gsa and Gic2 genes. The PCR primers for the Gsa gene included (1) 5'-AAATGATCCAA-ACTCGTTCAATGAT3' (sense) and (2) 5'-ACGTGAAATTTCCACAG-CGCAGGTTAAGTGGC-3' (antisense). The PCR primers for the Gic2 gene included (1) 5'-CTCTCGAATTCCTTGAAAGACCATGGC-GAAC-3' (sense) and (2) 5'-ATATGGATCCTGGTCAGCCCAGAGCCT-CGG-3' (antisense).

PCR fragments were then subcloned into pGEM Z3 or 4Z plasmid DNA (Promega, Madison, WI). Linearizing the plasmid constructs with proper restriction enzymes, we synthesized sense and antisense single-strand RNA from Gsa and Gic2 clones using either Sp6 or T7 RNA polymerase. After synthesis, the riboprobes were gel purified to ensure that the full length of the riboprobe was used in the hybridization reaction. The antisense RNA was used as riboprobe and sense RNA as control RNA (2–2,000 pg) in quantitative RNase protection assays.

RNase protection assay. In vitro transcription was performed to synthesize 32P-labeled riboprobes with specific activities ranging from 105 to 5 x 108 cpm/μg, using the gene constructs previously described. Total RNA (20 μg) from tissue and various amounts of in vitro–synthesized sense-strand control RNA were hybridized with 2 x 105 to 8 x 104 cpm probe in 20 μl of 10% formamide, 40 mM Hepes (pH 7.6), 400 mM NaCl, 1.0 mM EDTA for 12–16 h at 45°C. Digestion buffer (300 μl), containing 300 mM NaCl, 10 mM Tris-HCl, pH 7.4, 5 mM EDTA, and 20 μg of RNase A, and 3 U of T1 RNase per μg of total RNA, was then added and incubated for 30 min at 37°C. After treatment with proteinase K and extraction with phenol–chloroform, the RNase-resistant hybrids were precipitated and run on a 6% polyacrylamide–urea gel. As a result of the high specificity of the riboprobes, only one band was present on gel autoradiography. The Gsa and Gic2 mRNA signals were quantified by counting the excised gel band with a beta counter. After counting, the amount of control RNA could be expressed as cpm/μg control RNA. These data were used to quantify mRNA levels in myocardial tissue (fmol of specific RNA per mg of total RNA). The cardiac content of Gsa and Gic2 mRNAs was calculated from the ratio of their signal to the signal from their sense-strand control RNA in the same hybridization reaction. A mammalian 18S riboprobe (400 cpm; plasmid construct from Ambion, Austin, TX) was used together with Gsa and Gic2 riboprobes in the hybridizations to assess the loading and hybridization conditions for each tissue sample. The high yield and very low specific activity of the 18S riboprobe (5 x 105 to 8 x 104 cpm/μg; Megascript, Ambion) was obtained to ensure accurate measurement of the 18S transcript from 20 μg of total RNA. RNase resistance was <1%, as checked by complete digestion of single-strand antisense riboprobe plus 40 μg of transfer RNA (yeast) with RNase A and T1.

β-Adrenergic Receptor kinase activity. β-Adrenergic receptor kinase enzymatic activity was determined using light-dependent phosphorylation of rhodopsin (29, 30). We purified rhodopsin from rod outer segments obtained from dark-adapted calf retina. Light-dependent phosphorylation of purified rhodopsin was first tested by using recombinant β-adrenergic receptor kinase (a gift from Dr. J. L. Benovic, Thomas Jefferson University, Philadelphia, PA ). 1 g of left ventricle was homogenized in 9 ml of lysis buffer (50 mM Tris-Cl, pH 7.5, 5 mM EDTA, 10 μg/ml benzamidine, 20 μg/ml leupeptin, 40 μg/ml PMSF, and 5 μg/ml pepstatin A) and centrifuged at 45,000 g for 30 min. The pellet was resuspended in 4 ml of lysis buffer with 250 mM NaCl (used to dissociate membrane-associated β-adrenergic receptor kinase) and homogenized again in a power-driven glass rotor (4°C). The pellet suspension was then centrifuged, and ion exchange columns (Amicon) were used to remove NaCl from the supernatant of the pellet suspension. Both the supernatant and the supernatant of the pellet suspension then underwent DEAE–Sephacel column purification to eliminate endogenous kinases that could contaminate β-adrenergic receptor kinase–dependent phosphorylation. Both supernatant and pellet fractions were independently column purified.

β-Adrenergic receptor kinase–dependent phosphorylation was measured by incubating 100 μg of protein from either fraction with 250 pmol of rhodopsin in buffer containing 18 mM Tris-HCl, 1.8 mM EDTA, 4.8 mM MgCl2, 73 μM ATP, and 2.9 cpm/nmol [γ32P]ATP. The β-adrenergic receptor kinase–dependent phosphorylation reaction was confirmed by adding protein kinase A inhibitor (Walsh inhibitor, 1 μM) and heparin (10 μg/ml) to the reaction. Heparin inhibited phosphorylation; protein kinase A inhibitor did not. Phosphorylation was light dependent. These experiments established that β-adrenergic receptor kinase was responsible for the phosphorylation. Protein concentrations for both pellet and supernatant were determined before and after DEAE–Sephacel purification, and the final enzyme activity was expressed as pmol of phosphate/min per mg of protein as well as per g of tissue. We have previously shown that 45,000-g centrifugation (30 min) provides a supernatant that contains <1% of the total cellular activity of β-nitrophenyl phosphatase (a sarcosomal membrane-associated enzyme), suggesting excellent separation of cytosolic from membrane components (31).

Samples of right atrium were prepared as previously described, and 200 μg of protein per sample was incubated with rhodopsin. There was insufficient right atrial tissue to determine soluble versus particulate compartmentation of β-adrenergic receptor kinase activity, so total activity was measured. Samples were electrophoresed on a 10% acrylamide gel that was stained with Coomassie blue and dried. Bands corresponding to rhodopsin were cut from the gel and counted in a scintillation counter.

Quantification of β-adrenergic receptor kinase, by immunoblotting. Assessment of left ventricular β-adrenergic receptor kinase content was conducted using standard SDS-PAGE and immunoblotting techniques (5, 20). An antibody specific for β-adrenergic receptor kinase, a purified bovine β-adrenergic receptor kinase, was provided by Dr. J. L. Benovic. Transmural left ventricular samples were placed in a lysis buffer containing 20 mM Tris-HCl (pH 7.5), 2 mM EDTA, 10 μg/ml benzamidine, 10 μg/ml leupeptin, 100 μg/ml PMSF, and 5 μg/ml peptatin A. Samples were then homogenized using a Tekmar Tissueemizer (Tekmar Co., Cincinnati, OH), and centrifuged, and resuspended by sonication in lysis buffer. 80 μg of protein from each left ventricular sample was mixed with Laemmli buffer, boiled, and electrophoresed on a 10% denaturing gel. Proteins were transferred to polyvinylidene difluoride paper (Immobolin-P; Millipore Corp., Milford, MA); transfer efficiency was determined by Ponceau staining. The membrane was blocked for 2 h in TBS containing 0.1% Tween 20 and 5% nonfat dry milk and developed by conventional methods using anti–β-adrenergic receptor kinase, antiseraum followed by exposure to horseradish peroxidase–linked anti–rabbit immunoglobulin (1:1,000 in TBS). The blots were developed by the enhanced chemiluminescence method, and bands were visualized after exposing blots to x-ray film. Densities of bands comigrating with purified bovine β-adrenergic receptor kinase, were quantified by densitometric scanning.

Statistics. Data are expressed as mean ±1 SD. Specific measurements were compared using Student’s t test for paired (heart rate responses before and after isoproterol treatment) or unpaired data (all other comparisons). The null hypothesis was rejected when P < 0.05 (two-tailed unless otherwise stated).

Results

Heart rate. Heart rate after cholinergic receptor blockade with glycopyrrolate, a long-acting muscarinic cholinergic antago-
nist, was decreased after bisoprolol treatment (control: 187±8 bpm; bisoprolol: 130±10 bpm; \( P < 0.003 \)). Maximal isoproterenol-stimulated heart rate was also decreased (control: 270±35 bpm; bisoprolol: 235±12 bpm; \( P = 0.03 \)). These data suggest that the animals were receiving an adequate amount of bisoprolol to obtain an inhibiting effect upon heart rate (Fig. 1, left panel).

\( \beta \)-Adrenergic receptor binding studies. Fig. 1 (right panel) shows the results of saturation binding isotherm experiments. Bisoprolol treatment was associated with upregulation of \( \beta \)-adrenergic receptor in the right atrium (control: 73±10 fmol/mg; bisoprolol: 90±11 fmol/mg; \( P = 0.025 \)) and in the left ventricle (control: 72±7 fmol/mg; bisoprolol: 95±26 fmol/mg; \( P = 0.035 \)). Data from the left ventricle represent mean values of two saturation isotherms per tissue per animal (\( n = 6 \)). Data from the right atrium represent a single experiment (triplicate points; eight concentrations of ICYP) from each animal (\( n = 6 \)). Bisoprolol treatment did not affect the \( K_d \) for ICYP in either the right atrium (control: 150±25 pM; bisoprolol: 167±20; \( P = NS \)) or the left ventricle (control: 85±23 pM; bisoprolol: 97±16 pM; \( P = NS \)). Mean \( r^2 \) values for the Scatchard analyses were 0.98. In left ventricular samples, competitive binding studies showed upregulation among both \( \beta_1 \)-adrenergic receptors (control: 51±6 fmol/mg; bisoprolol: 67±13 fmol/mg; \( P = 0.02 \)) and \( \beta_2 \)-adrenergic receptors (control: 21±3 fmol/mg; bisoprolol: 28±6 fmol/mg; \( P < 0.03 \)). The \( K_i \), for the antagonist was unchanged in either \( \beta_1 \)-adrenergic receptors (control: 1±1 \( \mu \)M; bisoprolol: 2±3 \( \mu \)M) or \( \beta_2 \)-adrenergic receptors (control: 7±8 nM; bisoprolol: 15±14 nM).

Adenylyl cyclase activity. Gs-dependent (GTP\( \gamma \)S) and catalyst-dependent (forskolin) stimulation of cAMP production were unchanged in the right atrium and left ventricle by bisoprolol treatment (Table I). However, \( \beta \)-adrenergic receptor–dependent stimulation of cAMP was increased twofold in left ventricular membranes from bisoprolol-treated animals (\( P < 0.0001 \)). Basal values were similar in both chambers from both groups. Thus, \( \beta \)-adrenergic receptor stimulation resulted in a substantial increase in net cAMP production in left ventricular membranes from bisoprolol-treated animals.

Quantification of Gs\( \alpha \) and Gs\( \alpha \) by immunoblotting. To determine whether a chronic reduction in myocardial \( \beta \)-adrenergic receptor activation was associated with altered levels of cardiac Gs\( \alpha \) and Gs\( \alpha \), quantitative immunoblotting was performed. Quantitative immunoblotting using purified antibodies against Gs\( \alpha \) showed reduced amounts of Gs\( \alpha \) in membranes from the bisoprolol-treated animals in both the right atrium and the left ventricle (Fig. 2; Tables II and III). The reduction was 39\% in the right atrium (\( P < 0.12 \)) and 55\% in the left ventricle (\( P = 0.01 \)). Quantitative immunoblotting, performed using a purified antibody specific for Gs\( \alpha \), showed reduced amounts of Gs\( \alpha \) in membranes from the bisoprolol-treated animals in both the right atrium and the left ventricle (Fig. 2; Tables II and III). The reduction was 42\% in the right atrium (\( P < 0.005 \)) and 59\% in the left ventricle (\( P = 0.0002 \)).

| Table I. Adenylyl Cyclase Activity after Bisoprolol Treatment |
|----------------|----------------|----------------|
|                | Right atrium   | Left ventricle |
|                | Con            | Bis            | \( P \)  | Con            | Bis            | \( P \)  |
| Basal          | 22±5           | 26±5           | NS     | 29±5           | 33±6           | NS     |
| Iso + GTP      | 40±7           | 47±12          | NS     | 56±5           | 113±10         | 0.0001 |
| GTP\( \gamma \)S | 169±15         | 171±9          | NS     | 224±24         | 222±46         | NS     |
| AIF            | 139±21         | 136±21         | NS     | 267±32         | 263±42         | NS     |
| Forsk          | 289±53         | 208±94         | NS     | 349±57         | 357±46         | NS     |

Data represent cAMP produced in pmol/mg per min ± 1 SD and are net values (basal subtracted). \( P \), control versus bisoprolol (unpaired, two-tailed \( t \) test). \( n = 6 \) for each group. ISO, 10 \( \mu \)M isoproterenol; GTP, 100 \( \mu \)M guanosine 5’-triphosphate; GTP\( \gamma \)S, 100 \( \mu \)M guanosine 5’-O-(3-thiotriphosphate); AIF, 100 \( \mu \)M aluminum fluoride; Forsk, 100 \( \mu \)M forskolin.
G-proteins was reduced in the right atrium and left ventricle after chronic reduction in β-adrenergic receptor activation. Furthermore, RNase protection assays showed that the mRNA content for both G-proteins was reduced in the left ventricle (Fig. 2; Table III). Gsα mRNA content was reduced by 44% (P = 0.01), and Gia2 mRNA content was reduced by 30% (P = 0.048).

β-Adrenergic receptor agonist affinity. In left ventricular membranes, the proportion of β-adrenergic receptors showing high affinity binding for (−)-isoproterenol was unchanged by bisoprolol treatment (control: 46±12%; bisoprolol: 34±13%; P = NS; Figs. 3 and 4). In the absence of added guanine nucleotides, receptors displaying high affinity binding had a similar Kᵢ for isoproterenol (control: 9±6 nM; bisoprolol: 10±14 nM), and receptors displaying low affinity binding for isoproterenol also had a similar Kᵢ (control: 0.8±0.7 μM; bisoprolol: 0.8±0.6 μM). However, a difference in affinity state was observed in the presence of nonhydrolyzable GTP analogs (Fig. 3). Left ventricular membranes from control animals showed the expected shift to low affinity agonist binding when either Gpp[NH]p (data not shown) or GTPγS was added, but left ventricular membranes from bisoprolol-treated animals were resistant to uncoupling (Figs. 3 and 4). Thus, after bisoprolol treatment, the majority of β-adrenergic receptors showing high affinity agonist binding in the absence of GTP analogs continued to show high affinity agonist binding when GTP analogs were added (control: 1±1%; bisoprolol: 24±16%; P < 0.004; Figs. 3 and 4).

Quantification of β-adrenergic receptor kinase activity. To examine the activity of β-adrenergic receptor kinase, we used a modification of previously described methods (29, 30), in which the phosphorylation of rhodopsin, a reaction that requires β-adrenergic receptor kinase, is used. The phosphorylation is dependent upon light (Fig. 5) and is inhibited by heparin, a β-adrenergic receptor kinase inhibitor (data not shown). The modification we have used allows for determination of β-adrenergic receptor kinase activity in both the soluble and particulate fractions of membrane homogenates (30). Previous reports (17, 21) have not measured particulate β-adrenergic receptor kinase activity. In the present study chronic reduction in β-adrenergic receptor activation was associated with reduction in β-adrenergic receptor kinase activity in both soluble and particulate frac-

Values represent mean ±1 SD. G-protein levels were determined by quantitative immunoblotting and are expressed as pmol/g wet weight tissue. mRNA levels were determined by quantitative RNase protection assays and are expressed as specific mRNA in pmol/g total RNA. P values: control versus bisoprolol (unpaired; protein, two-tailed; mRNA, one-tailed). n = 6 for each group.

Quantification of β-adrenergic receptor kinase, by immunoblotting. To determine whether a chronic reduction in myocardial β-adrenergic receptor activation was associated with altered levels of β-adrenergic receptor kinase, protein content, immunoblotting was performed. Immunoblotting using a purified antibody against β-adrenergic receptor kinase, showed no change in immunologically detected β-adrenergic receptor kinase, protein content in left ventricular samples from animals treated with bisoprolol (control: 0.45±0.21 arbitrary densitometry units; bisoprolol: 0.45±0.13 arbitrary densitometry units; n = 6 both groups; P = 1.0). Right atrial β-adrenergic receptor kinase content was not assessed (insufficient material).

Discussion

To determine whether β-adrenergic receptor agonist activation influences G-protein expression and β-adrenergic receptor ki-
nase activity, we examined the effects of chronic β-adrenergic receptor antagonist treatment on components of the myocardial β-adrenergic receptor–G-protein–adenylyl cyclase pathway in porcine myocardium. We have found three new alterations in cardiac adrenergic signaling associated with chronic reduction in β-adrenergic receptor agonist activation. First, there is coordinate downregulation of Gia2 and Gsa mRNA and protein expression in the left ventricle; reduced G-protein content was also found in the right atrium. Second, after chronic reduction in β-adrenergic receptor activation, there is a twofold increase in β-adrenergic receptor–dependent stimulation of adenylyl cyclase and a persistent high affinity state of the β-adrenergic receptor in left ventricular membranes. Finally, there is a reduction in left ventricular β-adrenergic receptor kinase activity.

Downregulation of G-proteins. In the left ventricle, mRNA content for both Gia2 and Gsa was significantly decreased in treated pigs, to a degree that reflected reductions in protein expression. Thus, chronic reduction in β-adrenergic receptor activation is associated with coordinate decreases in mRNA and protein expression for Gsa and Gia2 in the left ventricle. Decreased Gia2 and Gsa protein and mRNA content in the left ventricle following chronic reduction of β-adrenergic receptor activation suggests that transcriptional regulation (or mRNA stability) may be an important determinant of G-protein expression and that such regulation may be linked to β-adrenergic receptor activation.

A recent study exploring the effects of sustained adrenergic activation on Gia2 found that isoproterenol infusion increased cardiac Gia2 protein content and transcription rates of Gia2 mRNA; message stability was unchanged (11). It is noteworthy that the Gia2 gene contains a putative cAMP response element (32). These data, taken together, suggest that Gia2 protein expression may be altered in a manner that reflects adrenergic activation. Thus, in the setting of sustained adrenergic activation, with its attendant increase in cAMP levels, gene transcription and thus protein expression are increased. One might speculate that, in settings of reduced adrenergic activation (β-adrenergic receptor antagonist treatment), reduced basal cAMP levels might have the reverse effect. Gia2 gene transcription and thus protein expression would be expected to decrease. Our data support this idea, since protein expression and Gia2 mRNA levels were both decreased, in association with chronic reduction in β-adrenergic receptor activation. Although β-adrenergic receptor–mediated cAMP production was increased in vitro, the heart rate response was diminished. This apparent paradox may reflect the continued presence of bisoprolol in vivo but not in vitro. Our speculation that reduced cAMP may be linked to Gia2 gene transcription implies that bisoprolol reduced β-adrenergic receptor–mediated cAMP in vivo.

We have previously reported reduced cardiac Gia2 mRNA and protein content in a porcine model of heart failure (5, 18, 19). Thus, chronic reduction in β-adrenergic receptor activation (bisoprolol treatment) and heart failure have similar effects upon Gia2 expression in the porcine heart. It is noteworthy that although heart failure is associated with increased levels of plasma norepinephrine, all measures of adenylyl cyclase are reduced, including reduced basal cAMP production (5). A possible explanation for reduced Gia2 expression in these two rather diverse settings is that both would be expected to have reduced cAMP response element activation and therefore reduced Gia2 gene transcription. It should be kept in mind, however, that human heart failure appears to be associated with increased Gia2 expression (7, 8); so the effects of heart failure on Gia expression may be model or species specific.

The Gsa gene lacks a cAMP response element (33); so in contrast to Gia2, a mechanism linking β-adrenergic receptor activation and Gs mRNA expression has not been established. Any potential link may not be direct since we have found similar reductions in Gsa mRNA and protein expression in porcine left ventricle in both heart failure (5) (sustained adrenergic activation) and β-adrenergic receptor antagonist treatment (attenuated adrenergic activation). It is difficult to advance a unifying hypothesis that encompasses these data while proposing adrenergic activation as the pivotal factor linking receptor activation with Gsa expression. The similarities between heart failure and β-adrenergic receptor blockade with respect to Gsa expression are intriguing. The precise mechanisms that result in reduced Gsa mRNA in the setting of reduced β-adrenergic receptor activation remain to be established. Based upon quantitative measures of mRNA content, we propose that pretranslational regulation of Gsa may provide a means to offset altered signal transduction induced by agents that inhibit agonist–receptor interactions in the heart.

There have been very few previous studies examining the effects of chronic β-adrenergic receptor antagonist treatment on cardiac G-protein expression, and none have used quantitative immunoblotting or RNase protection assays. Previous data come mostly from studies conducted on right atrial biopsies obtained from patients undergoing cardiac surgery (1). In general, these studies report no change in measures of G-protein expression. Differences between these prior studies and the present study may reflect the difficulty in obtaining true control tissue in the human studies, differences in species, and differences in the techniques used to measure G-protein expression.

Alterations in adenylyl cyclase activity after β-adrenergic receptor antagonist treatment have been reported by others (1). For example, a recent study (34) showed that propranolol, a nonselective β-adrenergic receptor antagonist, resulted in increased net isoproterenol-stimulated cAMP production in ca-
nine left ventricular myocardium after 7 d of treatment. These data are consistent with our findings with respect to adenylyl cyclase activity; however, no G-protein quantification was performed in that study. Chronic β-adrenergic receptor blockade may affect inhibitory as well as excitatory receptors. For example, it was recently shown that metoprolol administration for 10 d resulted in reduced numbers of muscarinic cholinergic (M2) receptors in rat heart and lung and reduced adenosine A1 receptors in rat brain (35). These data suggest that chronic reduction in β-adrenergic activation can affect multiple receptor pathways in multiple organs.

β-Adrenergic receptor kinase activity. The alterations in G-protein expression associated with chronic reduction in β-adrenergic receptor activation fail to provide a compelling reason why adenylyl cyclase activity shows a receptor-dependent doubling of cAMP production. Previous studies have indicated a specific effect on adenylyl cyclase activity similar to the one we describe in response to chronic β-adrenergic receptor antagonist treatment (1, 34). Potential mechanisms underlying this alteration in adrenergic signaling include alterations in receptor number, in receptor–agonist affinity, or in receptor–Gsα coupling.

An increase in β-adrenergic receptor number may have contributed to increased β-adrenergic receptor–mediated cAMP production, but since receptor number increased 32% and cAMP production increased 100%, additional factors may be important. The affinity of the β-adrenergic receptor for (−)-isoproterenol was not altered by bisoprolol treatment since the affinity constants for the high and low affinity states of the receptors were not altered. Furthermore, the proportion of receptors showing high affinity binding with (−)-isoproterenol was similar in control and bisoprolol-treated animals. The notable difference associated with bisoprolol treatment was the inability of nonhydrolyzable GTP analogs to uncouple the receptors from Gsα. Thus, after bisoprolol treatment a substantial residual number of the receptors exhibited persistent high affinity for (−)-isoproterenol. Based on the idea that stabilization of high affinity binding correlates with agonist response, this alteration would be expected to result in more efficient β-adrenergic receptor–mediated signal transduction and may play a mechanistic role in the observed increase in β-adrenergic receptor–dependent cAMP production. The relative inefficacy of GTP analogs to promote receptor–Gs uncoupling (the phenomenon of persistent high affinity agonist binding) has also been reported to occur in myocardial β-adrenergic receptors in hibernating mammals (36). The study by Morris et al. (36), like ours, found that persistent high affinity binding was associated with increased isoproterenol-stimulated cAMP production; β-adrenergic receptor kinase activity was not measured.

Finally, we asked two questions, one general and one specific. First, does the degree of β-adrenergic receptor activation affect myocardial β-adrenergic receptor kinase activity? And, more specifically, does reduced β-adrenergic receptor kinase activity underlie the observed alterations in adrenergic signaling associated with bisoprolol treatment? We found that reduced β-adrenergic receptor activation is associated with reduced β-adrenergic receptor kinase activity in the left ventricle. These data are particularly interesting in the context of recent reports showing that sustained β-adrenergic receptor activation (human heart failure) is associated with increased left ventricular β-adrenergic receptor kinase activity (17, 21). We have recently reported that left ventricular β-adrenergic receptor kinase activity is also increased in a porcine model of heart failure (37). Taken together, data from these prior studies and our present study suggest that there is an inverse relation between adrenergic receptor activation and β-adrenergic receptor kinase activity in the left ventricle. It is noteworthy that bisoprolol treatment was associated with increased isoproterenol-stimulated cAMP production in left ventricular but not right atrial myocardium. If altered β-adrenergic receptor kinase activity is an important factor in the mechanism for enhanced adrenergic signaling, one would expect altered levels of β-adrenergic receptor kinase in the left ventricle but not the right atrium. This is precisely what we found.

Although we found reduced enzymatic activity of the β-adrenergic receptor kinase, we found no change in immunologically detected β-adrenergic receptor kinase, content in left ventricular myocardium. There are several isoforms of G-protein–coupled receptor kinases, all potentially capable of promoting phosphorylation of rhodopsin (38). The present data do not identify the specific G-protein–coupled receptor kinase that accounts for reduced activity. Our immunoblotting data suggest that β-adrenergic receptor kinase, content is not altered by bisoprolol treatment. G-protein receptor kinase5 mRNA is expressed abundantly in mammalian heart (38). It is possible that reduced expression of G-protein–coupled receptor kinase, may contribute to the findings of the present study. This hypothesis cannot be tested until an antibody against G-protein receptor kinase, (or a specific enzymatic assay) becomes available to measure G-protein–coupled receptor kinase, protein content or activity. An alternative explanation is that the β-adrenergic receptor kinase, protein, although unchanged in amount, is functionally altered. The current data strongly support the hypothesis that left ventricular β-adrenergic receptor kinase activity is influenced by the degree of β-adrenergic receptor activation and that β-adrenergic receptor activity affects adrenergic signaling in the heart.

β-Adrenergic receptor kinase has been shown to phosphorylate only the β2-adrenergic receptor (39). Whether the β1-adrenergic receptor is phosphorylated by β-adrenergic receptor kinase in vivo is unknown. In the present study we found a significant increase in β2-adrenergic receptor number, and other data indicate that β2-adrenergic receptors may be more tightly coupled to adenylylcyclase than are β1-adrenergic receptors (1). Therefore, alterations in β-adrenergic receptor kinase activity are likely to be relevant in the present study. Our demonstration that cAMP production is increased only in the chamber where β-adrenergic receptor kinase activity is reduced under-
scores the potential biological importance of β-adrenergic receptor kinase activity in adrenergic signaling in vivo.

The precise mechanism by which alteration in β-adrenergic receptor activation may influence β-adrenergic receptor kinase protein expression is unknown. The β-adrenergic receptor kinase, gene sequence was recently published (40) and does not appear to contain a typical cAMP response element. However, the absence of a typical cAMP response element does not exclude the possibility that cAMP levels may influence β-adrenergic receptor kinase, gene expression. Finally, since G-protein–coupled receptor kinase, may contribute to the findings of the present study, it will be of interest to see whether the G-protein–coupled receptor kinase, gene contains cAMP response elements.

The association of persistent high affinity agonist binding (persistent β-adrenergic receptor–Gs coupling) with reduced β-adrenergic receptor kinase activity, an enzyme known to phosphorylate and thereby uncouple the β-adrenergic receptor from Gs, suggests that reduced β-adrenergic receptor kinase activity may play a role to enhance β-adrenergic receptor–mediated cAMP production after chronic reduction in β-adrenergic receptor activation. This implies that β-adrenergic receptor phosphorylation is a prerequisite for the GTP-induced rightward displacement of the isoproterenol competition curve.

In conclusion, we have shown that chronic reduction in myocardial β-adrenergic receptor activation (bisoprolol treatment) is associated with alternations in adrenergic signaling. Expression of cardiac G-proteins is reduced at the mRNA and protein levels. There is a striking increase in β-adrenergic receptor–mediated cAMP production in association with persistent high affinity agonist binding. Myocardial β-adrenergic receptor kinase activity is decreased, suggesting a previously unrecognized association between the degree of adrenergic activation and myocardial β-adrenergic receptor kinase expression. These data may have substantial relevance in clinical settings, since many patients are treated with such agents. Future studies aimed at the precise molecular mechanisms responsible for reduced β-adrenergic receptor kinase expression in the heart will provide data potentially useful for the management of adrenergic desensitization in clinical settings.

The heart appears to adapt in response to chronic β-adrenergic receptor antagonist administration in a manner that would be expected to offset reduced agonist stimulation. In many ways these adaptations appear to provide a desensitization-resistant state. The possibility that these adjustments may exist at the level of gene transcription of elements of the specific transduction pathway that they are aimed at interrupting is intriguing and suggests that homeostatic mechanisms play a role in the adaptive responses. It will be interesting to determine whether such changes are unique to the heart or instead reflect general features of adrenergic receptor function in many tissues.
