*J Clin Invest.* 2019. [https://doi.org/10.1172/JCI121491](https://doi.org/10.1172/JCI121491).

Across clinical trials, T cell expansion and persistence following adoptive cell transfer (ACT) have correlated with superior patient outcomes. Herein, we undertook a pan-cancer analysis to identify actionable ligand-receptor pairs capable of compromising T cell durability following ACT. We discovered that *FASLG*, the gene encoding the apoptosis-inducing ligand FasL, is overexpressed within the majority of human tumor microenvironments (TMEs). Further, we uncovered that Fas, the receptor for FasL, is highly expressed on patient-derived T cells used for clinical ACT. We hypothesized that a cognate Fas-FasL interaction within the TME might limit both T cell persistence and antitumor efficacy. We discovered that genetic engineering of Fas variants impaired in the ability to bind FADD functioned as dominant negative receptors (DNRs), preventing FasL-induced apoptosis in Fas-competent T cells. T cells coengineered with a Fas DNR and either a T cell receptor or chimeric antigen receptor exhibited enhanced persistence following ACT, resulting in superior antitumor efficacy against established solid and hematologic cancers. Despite increased longevity, Fas DNR–engineered T cells did not undergo aberrant expansion or mediate autoimmunity. Thus, T cell–intrinsic disruption of Fas signaling through genetic engineering represents a potentially universal strategy to enhance ACT efficacy across a broad range of human malignancies.

Introduction
Adoptive cell transfer (ACT) using genetically engineered T cells has entered the standard of care for patients with refractory B cell malignancies, including pediatric acute lymphoblastic leukemia (ALL) (1) and adult aggressive B cell lymphomas (2, 3). The efficacy of ACT in hematologic lymphoid malignancies has been consistently observed across clinical trials, regardless of institution, gene vector, or cell composition (4–9). However, responses to adoptive immunotherapy in patients with solid malignancies — collectively the leading cause of adult cancer-related deaths (10) — have been comparatively modest (11–15). Additionally, relapse is increasingly being recognized as a major clinical challenge following ACT for hematologic malignancies despite initially high overall response rates (1, 8). New strategies that enhance the potency of transferred T cells without increasing toxicity are therefore urgently needed if cell therapy is to serve a broader role in the treatment of human cancers (16).

Multiple variables may influence the success or failure of transferred T cells to mediate cancer regression in patients whose tumor cells uniformly express a target antigen (17). These can include the state of T cell differentiation (18) and local immune-suppressive factors present within the tumor-bearing host (19). Despite these complexities, one of the most consistent correlates of response observed in both hematologic (2, 4–6, 8) and solid cancers (11, 15, 20–22) has been the expansion and/or persistence of transferred T cells following infusion. Building upon this observation, we hypothesized that disruption of factors that negatively regulate T cell proliferation and survival might represent potentially actionable pathways to enhance adoptive immunotherapies. Several clinical trials have tested whether cell-extrinsic approaches can improve the persistence of adoptively transferred T cells, including coadministration of an immune checkpoint inhibitor (23, 24). However, these agents may not always efficiently enter the solid tumor microenvironment (25) and can cause nonspecific immune activation resulting in systemic toxicities that do not contribute to efficacy (26). We therefore pursued a cell-intrinsic strategy to enhance the function of tumor-specific T cells, thereby containing the risk of systemic toxicities and taking full advantage of the ability to reliably genetically engineer human T cells for clinical applications.

Using a pan-cancer analysis to identify candidate ligands that might limit the ability of T cells to expand and persist within the tumor microenvironment (TME), we hypothesized that disruption of Fas-FasL signaling could enhance T cell persistence. Fas-FasL signaling plays a critical role in T cell activation and proliferation and is negatively regulated by Fas death receptors (DRs) that serve as death-inducing signaling complexes (DISCs) (27). Fas-Ligand (FasL), the receptor for FasL, is highly expressed on patient-derived T cells used for clinical ACT. We hypothesized that a cognate Fas-FasL interaction within the TME might limit both T cell persistence and antitumor efficacy. We discovered that genetic engineering of Fas variants impaired in the ability to bind FADD functioned as dominant negative receptors (DNRs), preventing FasL-induced apoptosis in Fas-competent T cells. T cells coengineered with a Fas DNR and either a T cell receptor or chimeric antigen receptor exhibited enhanced persistence following ACT, resulting in superior antitumor efficacy against established solid and hematologic cancers. Despite increased longevity, Fas DNR–engineered T cells did not undergo aberrant expansion or mediate autoimmunity. Thus, T cell–intrinsic disruption of Fas signaling through genetic engineering represents a potentially universal strategy to enhance ACT efficacy across a broad range of human malignancies.

Across clinical trials, T cell expansion and persistence following adoptive cell transfer (ACT) have correlated with superior patient outcomes. Herein, we undertook a pan-cancer analysis to identify actionable ligand-receptor pairs capable of compromising T cell durability following ACT. We discovered that FASLG, the gene encoding the apoptosis-inducing ligand Fasl, is overexpressed within the majority of human tumor microenvironments (TMEs). Further, we uncovered that Fas, the receptor for FasL, is highly expressed on patient-derived T cells used for clinical ACT. We hypothesized that a cognate Fas-Fasl interaction within the TME might limit both T cell persistence and antitumor efficacy. We discovered that genetic engineering of Fas variants impaired in the ability to bind FADD functioned as dominant negative receptors (DNRs), preventing Fasl-induced apoptosis in Fas-competent T cells. T cells coengineered with a Fas DNR and either a T cell receptor or chimeric antigen receptor exhibited enhanced persistence following ACT, resulting in superior antitumor efficacy against established solid and hematologic cancers. Despite increased longevity, Fas DNR–engineered T cells did not undergo aberrant expansion or mediate autoimmunity. Thus, T cell–intrinsic disruption of Fas signaling through genetic engineering represents a potentially universal strategy to enhance ACT efficacy across a broad range of human malignancies.

Conflict of Interest: CAK, TNY, and NPR have submitted a US provisional patent (application 62/738,317) related to the Fas DNR technology described in this manuscript.

the tumor-bearing host, we discovered that the canonical apoptosis-inducing ligand FASLG is preferentially expressed in the majority of human tumor microenvironments (TMEs). Further, we found that most therapeutic T cells used for adoptive immunotherapy for both hematologic and solid cancers constitutively express Fas, the cognate receptor for FasL. Based on these findings, we developed a series of Fas dominant negative receptors (DNRs) that function in both primary mouse and human T cells to prevent FasL-induced apoptosis. Adoptively transferred Fas DNR-engineered T cells showed enhanced T cell persistence and antitumor immunity when co-engineered with either a T cell receptor (TCR) or chimeric antigen receptor (CAR) for the treatment of a solid or liquid cancer, respectively. Despite causing enhanced T cell persistence, this approach did not lead to uncontrolled T cell lymphoproliferation or cause off-target autoimmunity. Collectively, these results provide a potentially universal strategy to enhance the durability and survivability of adoptively transferred T cells for the treatment of a wide range of human malignancies following ACT.

Results

**Human TMEs overexpress the death-inducing ligand FASLG.** Across human ACT clinical trials for both hematologic and solid cancers, in vivo T cell expansion and persistence have positively correlated with clinical responses (4–6, 11, 21). These observations led us to hypothesize that disruption of pathways that impair T cell proliferation and survival might represent exploitable targets for improving outcomes following adoptive transfer. To determine whether ligands that negatively modulate T cell proliferation and survival are enriched within human TMEs, we compared RNA-Seq data from healthy donors (HDs), including central memory (TCM) cells, effector memory (TEM) cells, and effector memory T cells coexpressing CD45RA (TEMRA) (31, 32). With apheresis products used to generate therapeutic T cells for ACT from patients with melanoma or aggressive B cell lymphomas (diffuse large B cell lymphoma [DLBCL]), we analyzed both the distribution of CD8α⁺ T cell subsets and the frequency of Fas expression on these subsets. Comparison was made with circulating T cells obtained from a group of age-matched HDs. Consistent with previous reports, we found high expression of Fas on the T CM, T EM, and T EMRA subsets (Figure 1, D and E). Additionally, we discovered that the frequency of Fas naïve CD8α⁺ T cells (T N) in cancer patients was significantly lower than found in HDs (Figure 1F). The depletion of T N cells likely reflected the influence of prior immune-stimulating and lymphodepleting therapies in the cancer patients analyzed (6, 33, 34). Thus, a significant proportion of human T cells used for ACT express a known death receptor whose cognate ligand might be expressed in the TME.

**Fas DNRs prevent T cells from undergoing FasL-mediated apoptosis.** Our findings indicated that patient-derived T cells used for adoptive immunotherapy are skewed toward Fas-expressing subsets, which are subsequently transferred into FASLG-enriched TMEs. Based on these data, we next investigated whether disruption of Fas signaling within adoptively transferred T cells might prevent their apoptosis and improve in vivo persistence. In addition to triggering T cell apoptosis, FasL is also an essential effector molecule for T cell-mediated tumor killing (35). Further, systemic administration of either an anti-FasL antibody or Fas-Fc fusion protein might induce toxicities, including development of a lymphoproliferative syndrome and accumulation of an abnormal population of double-negative (DN) CD3⁺CD220⁻CD4⁻CD8⁻TCRα/β⁻ lymphocytes (36, 37). For these
reasons, we pursued a cell-intrinsic genetic engineering strategy to disable Fas signaling only within tumor-reactive T cells to maintain antitumor potency and minimize the risk of systemic toxicity.

Physiologically, FasL initiates apoptotic signaling by first inducing oligomerization of Fas receptors into trimers or larger oligomers at the cell membrane (Figure 2A) (38). Fas oligomers recruit the intracellular adaptor molecule Fas-associated via death domain (FADD) through homotypic death domains (DDs) present in each molecule (39, 40). Aggregation of FADD recruits the cysteine-aspartic acid protease procaspase-8 (41) through homologous death effector domains in each molecule, forming a death-inducing signaling complex that can initiate the apoptotic signaling cascade (42). Based on this mechanism of action, we hypothesized that overexpression of mutated Fas variants genetically altered to prevent FADD binding would function as DNRs when expressed in Fas-competent WT T cells used for adoptive immunotherapy. Presently, virus-based constructs are the most commonly used methods to stably modify human T cells for clinical application (43). We created a series of retroviral constructs encoding the murine Fas sequence in which either an asparagine residue was substituted for an isoleucine at position 246 of the DD (FasI246N; a naturally occurring mutant of murine Fas that is unable to bind FADD) (44) or a Fas mutant in which the majority of the intracellular DD was truncated (del aa222–306; FasΔDD) to prevent FADD binding (Supplemental Figure 1A and Figure 2A). As controls, we generated both an empty vector construct and a construct encoding the complete WT sequence of Fas (Fas WT). To identify transduced cells, all vectors contained a Thy1.1 reporter separated from Fas using a Thosea asigna virus 2A self-cleaving peptide (T2A) sequence.
T cells were isolated from Fas-competent WT mice; activated by anti-CD3/CD28 antibodies in the presence of IL-2; and transduced with the empty, FasWT, FasI246N, or FasΔDD construct (Figure 2B). Phenotypic analysis 6 days following activation and transduction revealed high transduction efficiencies for all constructs as measured by Thy1.1 reporter expression (Supplemental Figure 1, B and C). Notably, ectopic Fas expression was measurably higher than endogenous levels of Fas expression for constructs containing either the WT (6.8-fold higher Fas MFI) or mutant Fas variants (43-fold and 98-fold higher Fas MFI for FasI246N and FasΔDD, respectively; Supplemental Figure 1, B and D).

After 6 days in culture, transduced T cells were stimulated with recombinant FasL molecules oligomerized through a leucine zipper domain (lz-FasL) to mimic the function of membrane-bound FasL (45) or left untreated as controls. In the absence of lz-FasL, T cells transduced with each of the constructs remained similarly viable. Ectopic Fas expression was measurable at 8 and 18 μg/ml (Figure 2C). In the presence of lz-FasL, T cells transduced with WT Fas and empty vector were killed at the expected rate (Figure 2D). In contrast, T cells transduced with FasI246N or FasΔDD constructs were resistant to apoptosis, with annexin V+PI+ frequencies not significantly different from controls (Figure 2D). These results suggest that FasI246N and FasΔDD constructs can prevent apoptosis in response to FasL-mediated signals.

Figure 2. FasL-mediated apoptosis is prevented in T cells engineered with Fas DNRs. (A) Schematic representation of physiologic Fas signaling and design of 2 murine Fas DNRs. Fas DNRs were designed to prevent recruitment of FADD by either (i) substitution of an asparagine for an isoleucine residue at position 246 of the DD (FasI246N) or (ii) truncation of the majority of the intracellular DD (FasΔDD). WT Fas (FasWT) and an empty vector were used as controls. Receptors were cloned into a retroviral bicistronic vector containing a Thy1.1 reporter. EC, extracellular domain; TM, transmembrane domain. (B) Experimental timeline for the stimulation, retroviral transduction, and testing of lz-FasL-mediated apoptosis of CD8α+ T cells modified with Fas constructs or an empty vector control. (C) Representative FACS plots and (D) summary bar graph showing the frequency of apoptotic annexin V+PI+ transduced T cells at rest and 6 hours following exposure to lz-FasL (50 ng ml−1). Results are shown after gating on transduced Thy1.1+ cells. Data are representative of 6 independently performed experiments and displayed as mean ± SEM with n = 3 per condition. ***P < 0.001, 2-way ANOVA.
indicated that the DNR remained functionally intact over time (Supplemental Figure 3, A and B). Further, Sanger sequencing of serially restimulated, Fas I246N-transduced T cells showed no evidence of reversion of the I246N point mutation to the WT Fas sequence (Supplemental Figure 3, C and D). Thus, overexpression of Fas variants disabled in their ability to bind FADD function in a dominant negative manner to prevent FasL-mediated apoptosis in WT T cells.

Finally, we sought to ascertain whether the Fas DNRs afforded protection from other apoptosis-inducing stimuli that adoptively transferred T cells might encounter in vivo. These include activation-induced cell death (AICD), cytokine withdrawal, and proximity to tumor cells. For these assays, we utilized pmel-1 T cells specific for the cancer antigen gp100 and B16 melanoma engineered to express human gp100 (B16 cells). Although B16 cells did not express FasL at rest, FasL expression was measurably upregulated following incubation with IFN-γ (Supplemental Figure 4). We found that pmel-1 T cells transduced with FasΔDD were equally protected from apoptosis triggered by either lz-FasL or tumor coculture (Supplemental Figure 5). By contrast, transduction of T cells with FasΔDD resulted in significantly greater cell viability following exposure to lz-FasL, indicating that the DNR remained functionally intact over time (Supplemental Figure 3, A and B). Further, Sanger sequencing of serially restimulated, FasΔDD-transduced T cells showed no evidence of reversion of the I246N point mutation to the WT Fas sequence (Supplemental Figure 3, C and D). Thus, overexpression of Fas variants disabled in their ability to bind FADD function in a dominant negative manner to prevent FasL-mediated apoptosis in WT T cells.

In T cells modified with FasΔDD, we found neither functional nor genetic evidence of reversion to the WT sequence. We measured selective enrichment for T cells modified with FasΔDD compared with FasWT following serial in vitro restimulations, which indicated that the DNR remained functionally intact over time (Supplemental Figure 3, A and B). Further, Sanger sequencing of serially restimulated, FasΔDD-transduced T cells showed no evidence of reversion of the I246N point mutation to the WT Fas sequence (Supplemental Figure 3, C and D). Thus, overexpression of Fas variants disabled in their ability to bind FADD function in a dominant negative manner to prevent FasL-mediated apoptosis in WT T cells.

Finally, we sought to ascertain whether the Fas DNRs afforded protection from other apoptosis-inducing stimuli that adoptively transferred T cells might encounter in vivo. These include activation-induced cell death (AICD), cytokine withdrawal, and proximity to tumor cells. For these assays, we utilized pmel-1 T cells specific for the cancer antigen gp100 and B16 melanoma engineered to express human gp100 (B16 cells). Although B16 cells did not express FasL at rest, FasL expression was measurably upregulated following incubation with IFN-γ (Supplemental Figure 4). We found that pmel-1 T cells transduced with FasΔDD were equally protected from apoptosis triggered by either lz-FasL or tumor coculture (Supplemental Figure 5). By contrast, transduction of T cells with FasΔDD resulted in significantly greater cell viability following exposure to lz-FasL.
AIDC induction through anti-CD3/CD28 restimulation or acute cytokine withdrawal relative to cells modified with Fas\textsuperscript{DD}. These findings were potentially attributable to the ability of the Fas\textsuperscript{DD} variant to bind to FADD with reduced efficiency under certain conditions (46). We therefore subsequently focused exclusively on the Fas\textsuperscript{DD} DNR for all in vivo experiments given its superior functional attributes. This permitted us to more clearly determine the influence of removing Fas signaling on the in vivo function of adoptively transferred T cells.

**Adoptive transfer of T cells engineered with Fas DNR results in superior persistence.** Having established that modification with Fas\textsuperscript{DD} prevented T cell apoptosis in vitro across a diverse range of apoptosis-inducing stimuli, we sought next to determine whether engineering with this Fas DNR resulted in superior in vivo persistence following adoptive transfer. We therefore adoptively transferred congenically marked, gene-modified pmel-1 T cells into sublethally irradiated Thy1.1\textsuperscript{+} C57BL/6 (B6) mice to induce homeostatic proliferation, and measured the expansion and persistence of transferred cells over time. T cells transduced with Fas\textsuperscript{DD} or empty vector control were identified by expression of the Thy1.1 reporter gene. To measure T cell proliferation, we co-stained for the cellular proliferation marker Ki-67.

One day after transfer, we found that Fas\textsuperscript{DD}, and empty vector-modified pmel-1 T cells engrafted at similar levels and almost uniformly expressed Ki-67 (Figure 3, A-C). Beginning within 3 days of transfer, we measured a multi-log expansion of both populations of modified cells. However, at the peak of expansion, we noted an approximately 50-fold greater increase in the numbers of Fas\textsuperscript{DD}-modified T cells relative to control-modified cells. This in turn led to a more than 10-fold-higher level of persistence of Fas DNR-modified T cells on day 30 (Figure 3, A and B). Over time, we measured a comparable reduction in Ki-67 expression on both engineered T cell populations (Figure 3C), which correlated with reconstitution of the host’s endogenous T cell compartment. These data suggested that the in vivo proliferation was comparable between the two engineered T cell populations. However, Fas DNR-modified T cells demonstrated superior overall expansion and intermediate-term persistence, likely through a reduction in apoptosis.

We next sought to ascertain whether genetic modification with the Fas DNR resulted in superior T cell persistence within the TME. To ensure that modified T cells were exposed to the same microenvironmental factors within any given tumor, we performed a coinfiltration experiment. Congenically distinguishable pmel-1 T cells were obtained from either a Ly5.1–Thy1.1– or Ly5.1+Thy1.1– background. Cells were transduced with the Fas\textsuperscript{DD} DNR or a Thy1.1-expressing empty vector control, respectively. Transduced T cells were subsequently purified using anti-Thy1.1 microbeads, recombined at a roughly 1:1 ratio, then co-infused into sublethally irradiated Ly5.1+Thy1.1+ mice bearing 10-day-established B16 melanoma tumors (Figure 3D). As is currently done in many ACT clinical trials for solid tumors, treated mice received a limited course of IL-2 following transfer (14, 15, 20, 47, 48). Seven days following infusion, both the spleens and tumors of recipient mice were harvested and analyzed for the presence of adoptively transferred, genetically modified Thy1.1+ pmel-1 T cells. We consistently found significant enrichment of Ly5.1+Thy1.1+ Fas\textsuperscript{DD}–modiﬁ ed T cells relative to Ly5.1 Thy1.1+ empty vector–modiﬁ ed T cells in both the spleen and tumor of recipient mice (Figure 3E; \( P < 0.01 \), \( P < 0.0001 \)). Together, these results indicated that genetic engineering with a Fas DNR enhanced T cell persistence in vivo both in the spleen and TME following adoptive cell transfer.

**ACT of Fas DNR-modified T cells does not result in an acquired ALPS phenotype.** Mice and humans with germline defects in com-
ponents of apoptotic signaling can develop profound alterations in normal lymphocyte homeostasis and development. These abnormalities, collectively referred to as autoimmune lymphoproliferative syndrome (ALPS), include the accumulation of an aberrant DN lymphocyte population, the development of autoantibodies, and impaired survival (49, 50). Given the potential safety concerns related to disabling normal Fas signaling in mature T cells, we performed long-term immune monitoring of animals that received FasDD-DNR-modified T cells more than 6 months prior (Figure 4A). This time point was chosen because mice with germline defects in Fas typically develop overt clinical manifestations within the first 3.5–5 months of life, depending on the background strain (51, 52). Using unmanipulated B6 WT and Fas-deficient lpr (B6-lpr) mice as respective negative and positive controls for the ALPS phenotype, we assessed the frequency of CD3+ B220+ lymphocytes in the spleens of mice that had previously received ACT of Thy1.1+ Vjβ13+ pmel-1 T cells modified with the FasDD DNR or empty vector control. As expected, the spleens of B6-lpr mice exhibited a significant accumulation of abnormal CD3+ B220+ lymphocytes relative to WT controls (Figure 4, B and C; P < 0.05, P = 0.001). By contrast, there was no significant increase in this population in the mice receiving T cells modified with either empty vector or Fas DNR. To exclude the possibility of transformation of the modified T cell population, we assessed the long-term persistence and phenotype of transferred Vjβ13+ Thy1.1+ engineered T cells. Consistent with our findings at intermediate time points, we found that T cells engineered with FasDD DNR persisted at higher numbers than cells modified with the empty vector after more than 200 days (Figure 4, D and E; P < 0.05). Long-term-persisting Fas DNR–modified T cells maintained a conventional CD3+ B220+ phenotype. These data indicated that adaptively transferred pmel-1 T cells expressing the Fas DNR did not undergo abnormal lymphoproliferation in B6 hosts.

It was previously shown that expression of a transgenic TCR crossed to a Fas-deficient lpr background can limit the development of ALPS (53). Additionally, the B6 strain manifests lymphoproliferative symptoms at a slower rate compared with other strains (51, 52, 54). We therefore performed additional experiments to assess the safety of the FasDD DNR modification by adaptively transferring an open T cell repertoire genetically engineered with either Fas DNR or empty control into the ALPS-susceptible MRL-Mp strain. Fas-deficient mice on an ALPS-susceptible MRL-lpr background (MRL-lpr mice) develop autoantibodies, nephritis, and splenomegaly more severely and many months earlier than B6-lpr mice (Supplemental Figure 6A) (51, 52, 54).

To induce activation and expansion of adoptively transferred T cells in this model, we cotransduced open-repertoire T cells from the MRL-Mp mouse with a previously described second-generation anti-CD19 28Δ CAR (55) and the FasDD or control vector. Use of the anti-CD19 CAR in these experiments promoted strong in vivo proliferation of T cells through recognition of host CD19+ B cells. Of note, recently published data indicate that T cells modified with a CAR are still able to undergo stimulation through their TCR (56, 57).

We analyzed the spleens of MRL-Mp mice that received no cells (PBS), or anti-CD19 CAR+ T cells transduced with FasDD or empty control and compared these with the spleens of age-matched Fas-deficient MRL-lpr mice (Supplemental Figure 6C). We found that spleens from age-matched MRL-lpr mice weighed significantly more when compared with spleens from all other treatment groups. Importantly, we measured no difference in spleen sizes between PBS-treated mice and mice that received anti-CD19 CAR-transduced cells modified either with the FasDD or control. Flow cytometry analysis of splenocytes demonstrated a robust expansion of unusual DN CD3+ B220+ lymphocytes in the spleens of MRL-lpr mice that collectively accounted for more than 30% of all lymphocytes (Supplemental Figure 6, D and E). By contrast, the frequency of CD3+ B220+ lymphocytes in the empty vector and FasDD T cell–treated mice was similar to levels observed in the PBS control mice.

To assess for the development of autoimmunity, we performed serum analysis of all treated animals using samples from MRL-lpr mice as a positive control. We found that mice that received anti-CD19 CAR+ T cells modified with FasDD or empty vector had low antinuclear and anti-dsDNA antibody titers comparable to the PBS control (Supplemental Figure 6F). In contrast, serum from the MRL-lpr positive control mice demonstrated high titers of both types of autoantibodies.
In the absence of uncontrolled lymphoproliferation and the formation of autoantibodies, we found that anti-CD19 CAR+ T cells cotransduced with Fas DNR persisted at significantly higher levels in the spleens of recipient MRL-Mp mice compared with control-modified anti-CD19 CAR+ T cells (Supplemental Figure 6G). Further, the persistent Fas DNR−modified CAR+ T cells did not acquire a greater proportion of aberrant CD3+ B220+ cells compared with control-modified CAR+ cells (Supplemental Figure 6H). These results directly mirrored our findings using FasΔDD-modified pmel-1 T cells transferred into B6 hosts (Figure 4, D and E).

Finally, to assess whether the ALPS-susceptible MRL-Mp recipient mice developed lung pathology following adoptive transfer
of Fas DNR-modified T cells, we performed a blinded pathologic assessment of H&E-stained lung specimens. Consistent with previous reports (36), we found that the Fas-deficient MRL-lpr mice developed a dense mononuclear cell inflammatory lung infiltrate in the perivascular and peribronchiorial regions (Supplemental Figure 7, A and B). By contrast, mice treated with FasΔDNR, or control-modified T cells did not display evidence of an increased inflammatory infiltrate relative to PBS-treated control injection. Further, we observed no evidence of pulmonary fibrosis.

Together, these data in both the B6 and MRL-Mp strains demonstrate that despite the augmented survival of the FasΔDNR DNR T cells, there was no evidence of uncontrolled lymphooaccumulation, formation of a Thy1.1+CD3+B220+ population, or evidence of autoimmunity. Based on these data, we conclude that infusion of mature T cells impaired in Fas signaling does not result in an acquired lymphoproliferative phenotype.

**T cell-intrinsic disruption of Fas signaling enhances antitumor efficacy following ACT.** Having established that adoptively transferred T cells engineered with a Fas DNR results in enhanced persistence without long-term toxicity, we next evaluated the antitumor efficacy of these cells. We recently discovered that Fas stimulation can induce non-apoptotic Akt/mTOR signaling, resulting in augmented T cell differentiation (58–60). Consistent with our previous results, we found that exposure to Iz-FasL caused a dose-dependent increase in phosphorylated Akt (pS473) and p56ΔDD or p56+ΔDD in T cells transduced with an empty vector control (Supplemental Figure 8, A and B). Expansion of control-modified cells resulted in an accumulation of TCM-like cells with a reduced capacity to produce IL-2 (Supplemental Figure 8, C and D). By contrast, T cells transduced with a Fas DNR did not increase Akt or p56 phosphorylation following Iz-FasL stimulation and were protected from augmented Akt-mediated T cell differentiation. Consequently, Fas DNR-modified T cells retained a predominantly TEM-like phenotype and the capacity to produce IL-2. In several different animal models (32, 61–64) and human clinical trials (11, 65), transfer of TCM-like cells was associated with superior tumor regression compared with transfer of TEM-like cells. To control for the variable of T cell differentiation status, pmel-1 T cells transduced with FasΔDNR or an empty vector were enriched to greater than 97% purity for TCM-like cells by FACS sorting for Thy1.1+CD3+B220+ cells immediately prior to cell infusion (Figure 5A). Purified TCM-like cells were subsequently transferred into sublethally irradiated B6 mice bearing established B16 tumors. Treated mice also received IL-2 by i.p. injection. We found that adoptive transfer of tumor-specific TCM cells modified with the Fas DNR resulted in superior tumor regression and animal survival compared with control-modified T cells (Figure 5, B and C; P < 0.05).

We next sought to extend our treatment findings using an independent tumor model in which a hematologic malignancy was targeted with a CAR. We utilized a recently developed syngeneic B cell ALL (B-ALL) line driven by the physiologically relevant E2a-PBX translocation in a treatment model using a murine second-generation 28ζ anti-CD19 CAR (57, 66). We specifically chose a syngeneic model over the more commonly used xenogeneic anti-CD19 CAR treatment models for two reasons. First, we wished to ensure that the transferred T cells were fully responsive to host-derived FasL in addition to FasL expression by tumor cells and the adoptively transferred T cells. Second, we wished to avoid the potentially confounding influence of xenogeneic reactivity on AICD induction in the transferred T cells.

We first established that dual transduction of B6 CD8α+ T cells with retroviral constructs containing the FasΔDD or empty vector and anti-CD19 CAR was feasible (Figure 6, A and B). Using protein L to identify CAR-transduced T cells (67), we found that cotransduction efficiencies were similarly efficient using FasΔDD and the empty vector control following Thy1.1 bead enrichment. Next, we measured how the cotransduced anti-CD19 CAR T cells responded to various apoptosis-inducing stimuli, including exogenous FasL, cytokine withdrawal, AICD, and exposure to antigen-expressing B-ALL tumor cells (Figure 6C). Similar to our results using TCR-expressing pmel-1 T cells, we found that the expression of FasΔDD protected CAR-modified T cells from each of these death-inducing stimuli relative to empty vector control-transduced CAR+ T cells.

We next tested whether coexpression of a Fas DNR in CAR-modified T cells resulted in higher persistence and superior antitumor efficacy in comparison to empty-transduced CAR-modified T cells, as observed in the pmel-1 TCR transgenic/B16 melanoma model. We infused FasΔDD or empty Thy1.1+ anti-CD19 CAR+ CD8α+ T cells into sublethally irradiated B6 mice bearing 4-day-established E2a-PBX B-ALL (Figure 6D). Treated mice received daily IL-2 injections for 3 days to support expansion of the adoptively transferred T cells. Fourteen days following cell infusion, we analyzed the spleens and BM, two disease sites for E2a-PBX B-ALL, for persistence of the adoptively transferred cells. We measured higher levels of Thy1.1+ FasΔDD cells in both disease sites in comparison to mice that received empty vector-transduced T cells (Figure 6E). E2a-PBX leukemia expresses classic pre-B-ALL markers, including CD19, B220, and CD93 (66). As shown in Figure 6F, we found that the BM in untreated (PBS) and empty vector–treated mice contained roughly 70% leukemia cells 14 days after T cell treatment. However, the mice that received FasΔDD-modified cells contained less than 1% leukemia cells in the BM. These data indicated that CAR+ T cells expressing the Fas DNR cells were able to mediate superior leukemia clearance relative to empty vector–transduced T cells.

Finally, we analyzed the survival of leukemia-bearing mice after adoptive transfer of two different doses of second-generation 28ζ anti-CD19 CAR-transduced T cells comodified with FasΔDD or empty control. In order to provide for a treatment window, we intentionally transferred doses of CAR-modified T cells previously shown to be subtherapeutic in this model (57). At a higher cell dose (3×10⁶ CAR+ cells), we found that adoptive transfer of either control- or FasΔDD-modified CAR+ T cells resulted in significantly improved animal survival compared with mice that did not receive treatment (Figure 6G, left). However, whereas all mice that received the Fas DNR-modified CAR+ T cells survived, mice that received control-modified CAR+ T cells did not survive longer than 55 days. At a further de-escalated dose of CAR+ cells (2×10⁶), Fas DNR-modified T cells continued to provide long-term survival in 100% of treated mice, while control-modified T cells entirely lost efficacy (Figure 6G, right). Previous reports have demonstrated that 4-1BB-containing second-generation CARs express higher
levels of antiapoptotic proteins compared with CARs containing a CD28 domain (68). We did not test in these experiments whether the Fas DNR could also enhance the function of a 4-1BB–containing CAR. Nevertheless, these data in the solid cancer B16 melanoma and hematologic E2a-PBX leukemia models indicate that Fas DNR expression in adoptively transferred T cells results in superior in vivo cellular persistence and antitumor efficacy regardless of whether the antigen-targeting structure is a TCR or 28ζ CAR.

**Genetic engineering with Fas DNRs protects human T cells from Fas-mediated apoptosis.** To determine the feasibility of engineering primary human T cells with Fas DNRs, we designed retroviral constructs encoding the human Fas sequence mutated to prevent FADD binding. This included a human Fas variant containing a point mutation substituting a valine for an aspartate residue at position 244 (hFasD244V) (69, 70) and human Fas with the majority of the intracellular DD truncated (del aa230–314; hFasΔDD) (Figure 7A) (69, 70). An empty vector was used as a negative control. Receptors were cloned into a bicistronic vector containing a Thy1.1 reporter. (B) Experimental timeline for the stimulation, retroviral transduction, and testing of lz-FasL–mediated apoptosis of human CD8+ T cells modified with FasD244V, FasΔDD, or an empty vector control. (C) Representative FACS plots (0 and 100 ng ml−1 lz-FasL) and (D) summary graph showing the frequency of live cells relative to the no lz-FasL condition 6 hours following exposure to titrated concentrations of lz-FasL. Results shown after gating on transduced (Thy1.1+) or untransduced (Thy1.1−) T cells. Data are displayed as mean ± SEM with n = 3 per condition and are representative of 3 independent experiments. *P < 0.05, Wilcoxon’s rank-sum test.

Figure 7. Genetic engineering with Fas DNR protects human T cells from FasL-induced apoptosis. (A) Schematic representation of physiologic Fas signaling and the design of 2 human Fas DNRs. Retrovirus-encoded human Fas DNRs were designed to prevent recruitment of FADD either by (i) substitution of a valine for an aspartic acid residue at position 244 of the DD (hFasD244V) or (ii) truncation of the majority of the human intracellular DD (hFasΔDD).
toxis. Thus, we conclude that genetic engineering with a Fas DNR protects primary human T cells from FasL-induced cell death, providing a new method to potentially protect adoptively transferred T cells within the human TME.

Discussion

Herein, we report the results of a pan-cancer analysis that suggested that a canonical death-inducing ligand, FASLG, is overexpressed within the majority of human cancer microenvironments. We further discovered that a significant proportion of human T cells used for adoptive immunotherapy express Fas, the cognate receptor for FasL. Based on these findings, we developed a cell-intrinsic strategy to “insulate” Fas-competent mouse and human T cells from FasL-induced apoptosis using genetic engineering with a series of Fas DNRs. Functionally, adoptively transferred Fas DNR-modified T cells exhibited greater persistence in both the periphery and tumors of tumor-bearing animals, resulting in superior tumor regression and overall survival in both solid and liquid syngeneic cancer models. Importantly, while T cells modified with Fas DNR exhibited enhanced survival relative to control-modified T cells as late as 6 months following transfer, we detected no evidence of uncontrolled lymphoproliferation or autoimmunity. These findings therefore provide a potentially universal gene engineering strategy to enhance the function of adoptively transferred T cells against a broad range of human malignancies, including both solid and hematologic cancers.

We previously reported that in addition to its canonical apoptosis-inducing functions, Fas can also promote mouse and human T cell differentiation in an Akt-dependent manner (58, 59). Consistent with these findings, we discovered that T cells transduced with Fas DNRs were protected from FasL-mediated induction of pAkt and pS6. Consequently, this block in Akt/mTOR signaling minimized T cell differentiation, promoting the accumulation of TCM-like cells that retained expression of the lymphoid homing marker CD62L and the capacity to produce IL-2. In multiple preclinical models (32, 61, 62, 64) and in retrospective analyses of human clinical trials (11, 65), infusion of TCM-like cells was associated with superior antitumor outcomes compared with TEM-like cells. We therefore compared the antitumor efficacy of phenotypically matched, FACS-sorted TCM-like cells modified with a Fas DNR or an empty vector control. We found that Fas DNR-modified TCM cells exhibited superior treatment efficacy compared with control-modified TCM cells. Mechanistically, we conclude that the dominant contributor of the enhanced in vivo antitumor efficacy we found using Fas DNR–modified T cells was attributable to the disruption of cell death and not the infusion of less-differentiated cells. These findings are also consistent with recent articles by Zhu et al., Horton et al., and Lakins et al. demonstrating that FasL-induced apoptosis of tumor-infiltrating lymphocytes limits the efficacy of immune checkpoint inhibitors (9, 71, 72).

While our analyses indicated that FASLG expression is enriched within the TMEs of many human tumors, they do not define which specific cell type is expressing the ligand. Using immunohistochemical protein staining, previous studies have demonstrated that FasL can be expressed directly on the surface of many of the solid cancers identified in our pan-cancer analysis. This includes cancers of the breast, colon, brain, kidney, and cervix (73, 74). Additionally, recent studies have also identified that FasL is expressed along the luminal surface of the neovascularure surrounding human ovarian and brain cancers, creating a tumor endothelial death barrier limiting T cell infiltration (73, 75). Further, it is possible that FasL can be expressed within the TME by cells of both the innate and adaptive immune system. This possibility has previously been shown by others (19) and is further suggested by our own analysis demonstrating a high degree of correlation between FASLG and many immune-related genes. Finally, our functional data demonstrate that Fas DNR modification also affords protection from other apoptosis-inducing stimuli. Thus, we conclude that the Fas DNR can enhance T cell survival to a broad range of potential FasL sources, including tumor cells, nontransformed cells in the TME, as well as T cells themselves.

Fas DNR now joins a list of other candidate DNRs with which a T cell might be modified to intrinsically disrupt signaling by immune-suppressive factors present within the TME, including TGF-β (76) and PD1-L1/L2 (77). Disruption of Fas using a short hairpin RNA approach has been reported in human T cells in vitro (78); however, due to the relatively poor efficiency of Fas knockdown, this approach required lengthy in vitro selection. Furthermore, the in vivo antitumor capacity of these cells was not tested. Germ line loss of function in Fas signaling can result in an autoimmune lymphoproliferative disease in both mice and humans, a potential safety consideration for the Fas DNR approach. Despite augmented survival of Fas−/−-modified T cells, we found no evidence of uncontrolled lymphoproliferation, formation of an aberrant CD3 T220 + lymphocyte population, or autoimmunity using 2 different mouse strains. This included performing adoptive transfer of a polyclonal T cell population into the ALPS-prone MRL-Mp strain. Based on these data, we conclude that infusion of mature T cells impaired in Fas signaling is unlikely to result in an acquired lymphoproliferative syndrome.

Although Fas is a critical mediator for initiating the extrinsic apoptotic signaling cascade, intrinsic apoptotic pathways remain intact in our cells. Thus, competition for homeostatic cytokines, neglect due to an absence of antigen, and T cell exhaustion may all contribute to regulating the homeostasis of Fas DNR cells in vivo. Despite these reassuring safety data in mice, refinement of this approach for clinical application will include the introduction of a suicide mechanism, such as a truncated EGFR upstream of the Fas DNR (79, 80) or an inducible caspase-9 variant (81).

In conclusion, we have discovered that the FasL/Fas pathway is poised to be activated in many patients receiving adoptive immunotherapy for the treatment of human cancers. We have developed DNRs that intrinsically abrogate the apoptosis-inducing functions of this pathway in primary mouse and human T cells. This engineered resistance to Fas-mediated apoptosis in turn led to enhanced in vivo cellular persistence and augmented antitumor efficacy in 2 different syngeneic models for the treatment of a B16 melanoma and a B-ALL using TCR- and CAR-modified T cells, respectively. These data lay the groundwork for a potential universal strategy to enhance the potency of adoptive immunotherapies against both solid and hematologic cancers.
Methods

The Cancer Genome Atlas pan-cancer bioinformatics analysis. RNA-Seq data from 26 human cancers from the Cancer Genome Atlas (TCGA) data set and matched normal tissues from the GTEx data set were collected and analyzed by UCSC Xena (82) in the form of normalized RSEM values. FASLG gene expression as normalized RSEM counts was analyzed in each. Statistics were corrected by Mann-Whitney U test. To identify genes positively correlated to FASLG expression, we ran a pre-ranked gene set enrichment against all KEGG pathways in the Molecular Signatures (MSigDB) database. Pearson’s correlation was performed on the top 1000 genes positively correlated to FASLG expression averaged across 26 TCGA histologies.

Human specimens. PBMCs were obtained from patients with melanoma and DLBCL enrolled in an adoptive immunotherapy clinical protocol, or from age- and sex-matched HDs.

Mice. Adult 6- to 12-week-old male or female B6 NCR (B6;Ly5.2) mice were purchased from Charles River Laboratories at NCI Frederick. B6.SJ- Ptprc^+/+ Ptpm1a^/+- (Ly5.1), B6.12957-Rag1^/lMm/Mom/J (Rag), B6.MRL-Fas^+/+ (B6-lpr), B6.Cg-Thy1.1^/CyTg(Trcra28b)8Rest/J (pmel-1; ref. 83), MRL/MpJ (MRL-Mp), and MRL/MpJ-Fas^+/+ (MRL-lpr) mice were purchased from the Jackson Laboratory. Where indicated, pmel-1 mice were crossed to a Ly5.1 or Rag background. All mice were maintained under specific pathogen–free conditions. Where indicated, pmel-1 mice were crossed to a Ly5.1 or Rag background. Untouched murine CD8α+ T cells were isolated from splenocytes using a MACS CD8α negative selection kit (Miltenyi Biotec) and stimulated in tissue culture–treated 24-well plates with plate-bound anti-CD3 (2 μg ml⁻¹, clone 145-2C11, BD Biosciences), soluble anti-CD28 (1 μg ml⁻¹, clone 37-51, BD Biosciences) and rhIL-2 (IL-2; 5 ng ml⁻¹, Prometheus). Pmel-1 T cells were stimulated in whole splenocyte cultures with 1 μg ml⁻¹ human gp100 25–33 peptide and IL-2 (5 ng ml⁻¹). Human PBMCs or CD8α+ T cells were stimulated with plate-bound anti-CD3 (1 μg ml⁻¹, clone OKT3, BD Biosciences) and soluble anti-CD28 (1 μg ml⁻¹, clone CD28.2, BD Biosciences) for 2 days, then treated with IL-2 (20 ng ml⁻¹) during the remainder of culture. Cells were stimulated for 24 hours before transduction with virally supernatant on days 1 and 2 of culture. On day 3 cells were removed from Retronectin-coated plates and returned to tissue culture–treated 24-well plates or flasks. Where noted cells were grown with either vehicle or the indicated concentrations of Iz-FasL, a recombinant form of oligomerized FasL (45, 59). Five to 6 days (for murine cells) or 10–11 days (for human cells) after stimulation, T cells were washed twice, plated at 1 × 10⁵ to 2 × 10⁶ cells/well in a 96-well plate with the indicated concentrations of Iz-FasL, and incubated at 37°C with 5% CO₂ for 6 or 24 hours. Cells were then washed twice and stained with either annexin V or PI. Live/Dead Fixable Dye (Thermo Fisher Scientific) as well as CD8α (clone 53-6.7, BD Biosciences) and Thy1.1 (clone H1S51, eBioscience).

Flow cytometry, intracellular cytokine staining, and phospho-flow. Cells were stained with fixable cell viability dye in PBS, then washed twice with FACS buffer. Human cells were stained with the following fluorochrome-conjugated antibodies: CD3 (UCHT1), CCR7 (3D12), CD45RA (HI100), CD45RO (UCHL1), CD28 (CD28.2), CD95 (DX2) (BD Biosciences); and CD27 (M-T271), CD62L (REG-56), CD8α (SK1), CD4 (OKT4) (BioLegend). Murine T cells, BM, and splenocytes were stained with the following antibodies: CD3 (clone 145-2C11), CD8α (clone 53-6.7), Vβ13 (MR12-3), Ly5.1 (A20), Ly5.2 (clone 104), CD62L (MEL-14), CD95 (Jo2), B220 (RA3-6B2) (BD Biosciences); CD44 (IM7), CD19 (6D5), CD93 (AA4.1) (BioLegend); Thy1.1 (H1S51, eBioscience). For anti-CD19 CAR detection (67) Biotin-Protein L (GenScript) was utilized.

For phospho-flow, cells were fixed and permeabilized using the BD Biosciences Phosflow reagents and following the manufacturer’s protocol. After permeabilization, cells were stained with pAkt (S473) (D9E) and pS6 (S235/236) (D57/2.2E) from Cell Signaling Technology. For intracellular cytokine staining, cells were stained for surface antibodies in FACS buffer, then fixed and permeabilized (BD Biosciences) and stained for IFN-γ (XMG1.2, BD Biosciences) and IL-2 (JES6-5H4, BioLegend). For FasL staining, tumour cells were incubated with vehicle (PBS) or murine IFN-γ (100 ng ml⁻¹, BioLegend) for 24 hours, then stained with Fasl (Kay-10) and H-2Db (KH95)
Sanger sequencing analysis. Genomic DNA from Thy1.1–enriched empty vector– or Fas DNR–engineered T cells was extracted using the AllPrep DNR/RNA Mini Kit (QIAGEN). Primers (IDT) were designed such that the forward primer was located in Fas upstream of the FasI246N point mutation and the reverse primer in the Thy1.1 reporter. After PCR amplification (Invitrogen) Sanger sequencing was performed by the NCI Sequencing Core Facility.  

ACT, T cell enumeration, and tumor treatment. For analysis of in vivo persistence, male or female B6 mice aged 6–12 weeks received 6 Gy total body irradiation. One day later, they were injected by tail vein injection with 5 × 10^6 congenically marked pmel-1 T cells transduced with a Thy1.1-containing reporter construct. Mice were sacrificed on the indicated days, and splenocytes were analyzed for homeostatic expansion of pmel-1 T cells.

For tumor treatment experiments, male or female B6 mice aged 6–12 weeks were injected with 5 × 10^6 cells of a previously described B16 melanoma line (86) that overexpresses the chimeric human/mouse gp100 antigen KYPQNDWLL (aa25–33) or 1 × 10^6 CD19+ E2a-PBX leukemia cells. Tumor-bearing mice received 5–6 Gy total body irradiation on the indicated days. Mice were left untreated as controls or received by tail vein injection the indicated doses of congenically marked pmel-1 or anti-CD19 CAR–transduced T cells modified with a Thy1.1-containing reporter construct. To analyze anti-CD19 CAR–transduced T cell persistence and leukemia burden, we sacrificed mice after 14 days and performed cellular analysis on the spleen and BM.

For experiments with MRL-Mp mice, female mice aged 8 weeks received 6 Gy total body irradiation. One day later, mice were injected with 3 × 10^6 anti-CD19 CAR–transduced CD8+ T cells also transduced with a Thy1.1-containing reporter construct. Age-matched MRL-lpr female mice were left unmanipulated as an ALPS positive control.

All transduced T cells were beaded-enriched to >92% purity using anti-Thy1.1 magnetic microbeads prior to infusion (Miltenyi Biotec). All treated mice received once-daily injections of 12 μg IL-2 i.p. for 3 days. All tumor measurements were performed in a blinded fashion by an independent investigator.

T cell and tumor cell coculture assay. After 5–6 days in culture, T cells were washed twice in PBS and plated in IL-2–free T cell media at 5 × 10^4 cells per well in a 96-well round-bottom plate. T cells were incubated either alone, with plate-bound anti-CD3/CD28 (2 μg ml^-1, each), with 1.5 × 10^6 B16-mhgp100 or E2a-PBX cells per well for an E/T of 1/3, or with 50–100 ng ml^-1 Lz-Fasl. Cells were cultured together for 6 or 24 hours before being washed and stained for cell viability.

ELISA assay. Analysis of serum anti-nuclear and anti-dsDNA antibodies was performed on serum diluted 1:5; ELISA was performed according to the manufacturer’s instructions (Alpha Diagnostic International).

Histopathology. Lung tissues were fixed in buffered 10% formalin and stained with H&E. Tissue sections were scored in a blinded manner by an interpreting pathologist. Scoring was as follows: 0, no specific findings; 1, mild infiltrates; 2, minimal infiltrates; 3, moderate infiltrates; 4, severe infiltrates.

Statistics. The products of perpendicular tumor diameters were plotted as the mean ± SEM for each data point; tumor treatment graphs were compared using Wilcoxon’s rank-sum test, and analysis of animal survival was assessed using log-rank Mantel-Cox test. For all other experiments, data were compared using either unpaired 2-tailed Student’s t test corrected for multiple comparisons by Bonferroni’s adjustment or repeated measures using 1- or 2-way ANOVA, as indicated. In all cases, P values less than 0.05 were considered significant. Statistics were calculated using GraphPad Prism 7 software.

Study approval. All anonymous NIH Blood Bank donors and cancer patients providing PBMC samples were enrolled in clinical trials approved by the NIH Clinical Center and NCI institutional review boards. Each patient signed an informed consent form and received a patient information form prior to participation. Animal experiments were approved by the Institutional Animal Care and Use Committees of the NCI and performed in accordance with NIH guidelines.

Data and materials availability. All data reported herein are recorded in the manuscript, or are available in the supplemental materials or through the publicly available databases TCGA (https://cancergenome.nih.gov/) and UCSC Xena (http://xena.ucsc.edu).

Author contributions. TNY, NPR, and CAK designed and conceived of all experiments and wrote and edited the manuscript. TNY and PHL performed all tissue culture, retroviral transduction, and immune-phenotyping experiments. SKV, DG, and RJK assisted in RNA-Seq analysis and experimental design. RE assisted in the design and generation of Fas DNR–engineered T cells. JF and LG assisted in experimental design and performing in vivo experiments. JNK and TJF provided in vivo reagents and helpful discussion on performing in vivo experiments. TNY, ZY, and AE performed in vivo experiments and all animal husbandry and colony management. AGC and RMS provided the Lz-FasL reagent and assisted with death assays and experimental design. BAA and JEH assisted with all bioinformatic analyses. All coauthors edited and commented on the final manuscript.

Acknowledgments. We thank K. Hanada for contributing the B16-mhgp100 melanoma cell line. We thank S. Patel, S.M. Sukumar, and C. Ouyang for thoughtful discussions; R. Somerville for assistance with patient sample collection; A. Mixon and S. Farid for expertise with cell sorting; B. Karim for histopathology analysis and helpful discussions; and M. Cam and A. Merchant for help with bioinformatics analysis. This work was funded by the National Cancer Institute, Center for Cancer Research (NPR and CAK). Additional funding was provided to CAK by the Parker Institute for Cancer Immunotherapy, Damon Runyon Cancer Research Foundation, William H. Goodwin and Alice Goodwin and the Commonwealth Foundation for Cancer Research, Center for Experimental Therapeutics at MSKCC, and MSKCC Core grant P30 CA008748.
