Poroma is a benign skin tumor exhibiting terminal sweat gland duct differentiation. The present study aimed to explore the potential role of gene fusions in the tumorigenesis of poromas. RNA sequencing and reverse transcription PCR identified highly recurrent YAP1-MAML2 and YAP1-NUTM1 fusions in poromas (92/104 lesions, 88.5%) and their rare malignant counterpart, porocarcinomas (7/11 lesions, 63.6%). A WWTR1-NUTM1 fusion was identified in a single lesion of poroma. Fluorescence in situ hybridization confirmed genomic rearrangements involving these genetic loci. Immunohistochemical staining could readily identify the YAP1 fusion products as nuclear expression of the N-terminal portion of YAP1 with a lack of the C-terminal portion. YAP1 and WWTR1, also known as YAP and TAZ, respectively, encode paralogous transcriptional activators of TEAD, which are negatively regulated by the Hippo signaling pathway. The YAP1 and WWTR1 fusions strongly transactivated a TEAD reporter and promoted anchorage-independent growth, confirming their tumorigenic roles. Our results demonstrate the frequent presence of transforming YAP1 fusions in poromas and porocarcinomas and suggest YAP1/TEAD-dependent transcription as a candidate therapeutic target against porocarcinoma.
Recurrence YAP1-MAML2 and YAP1-NUTM1 fusions in poroma and porocarcinoma

Poroma is a benign skin tumor exhibiting terminal sweat gland duct differentiation. The present study aimed to explore the potential role of gene fusions in the tumorigenesis of poromas. RNA sequencing and reverse transcription PCR identified highly recurrent YAP1-MAML2 and YAP1-NUTM1 fusions in poromas (92/104 lesions, 88.5%) and their rare malignant counterpart, porocarcinomas (7/11 lesions, 63.6%). A WWTR1-NUTM1 fusion was identified in a single lesion of poroma. Fluorescence in situ hybridization confirmed genomic rearrangements involving these genetic loci. Immunohistochemical staining could readily identify the YAP1 fusion products as nuclear expression of the N-terminal portion of YAPI with a lack of the C-terminal portion. YAPI and WWTR1, also known as YAP and TAZ, respectively, encode paralogous transcriptional activators of TEAD, which are negatively regulated by the Hippo signaling pathway. The YAPI and WWTR1 fusions strongly transactivated a TEAD reporter and promoted anchorage-independent growth, confirming their tumorigenic roles. Our results demonstrate the frequent presence of transforming YAPI fusions in poromas and porocarcinomas and suggest YAPI/TEAD-dependent transcription as a candidate therapeutic target against porocarcinoma.

Introduction
Poroma is a skin adnexal tumor exhibiting features of the terminal sweat gland duct (1, 2). It typically presents as a solitary sessile nodule on the soles and palms but may occur in any area where sweat glands are present. Histologically, poroma consists of monomorphic small basaloid cells and contains occasional ductal structures. Most commonly, the tumor is broadly connected to the epidermis and grows down into the dermis, forming broad anastomosing bands. Some lesions exhibit a spectrum of architectural variations that allows them to be classified into histological subtypes (Supplemental Figure 1) (2–6). Hidroacanthoma simplex represents an intraepidermal variant, whereas a dermal duct tumor is primarily confined to the dermis. Poroid hidradenoma presents as a discrete nodule centered in the dermis and shows characteristic solid and cystic components. Although poromas are relatively common, their genetic background has only been analyzed in a few studies. A recent targeted next-generation sequencing analysis of 6 poromas identified a number of mutations, including HRAS mutations as the sole recurrently mutated gene (7). However, the reported prevalence of HRAS mutations was limited to 17%, suggesting that poromas are a rather heterogeneous group of tumors in terms of genetic alterations (7, 8).

Porocarcinoma represents the rare malignant counterpart of poroma predominantly affecting elderly individuals (9–11). In contrast to poromas, porocarcinomas exhibit invasive growth, are prone to local recurrence, and may develop distant metastasis. Because of their rarity and lack of distinct clinical features, the diagnosis of porocarcinoma is often challenging. A subset of porocarcinomas is associated with benign poromas, a finding implying malignant transformation (2, 9, 11). Furthermore, porocarcinomas arising from longstanding poromas have been reported (9, 12). Apart from these, many porocarcinomas do not have a benign precursor component and thus may develop de novo (11, 13). A recent sequencing analysis of 5 porocarcinomas identified recurrent mutations in TP53, RB1, EGFR, and HRAS, but simultaneously revealed the molecular diversity of this rare type of tumor (8).

Given that mutations in known oncogenes and tumor suppressor genes are unlikely to underlie the tumorigenesis of a majority of poromas, we used RNA sequencing to explore the possible roles of gene fusions. Our analysis identified highly recurrent YAPI fusions in poromas and porocarcinomas and demonstrated their transforming activity.

Results and Discussion
To probe the possible tumorigenic roles of gene fusions in poroma, we subjected 12 formalin-fixed, paraffin-embedded poroma specimens to RNA sequencing. The analysis identified YAPI-MAML2 and the reciprocal MAML2-YAPI fusions in 4 lesions, YAPI-NUTM1 fusions in 3 lesions, and a WWTR1-NUTM1 fusion in 1 lesion (Supplemental Table 1). To expand on this finding, we examined
Interestingly, there appear to be associations between specific YAP1 fusion types and clinicopathological features. Hidroacanthoma simplex predominantly expressed the YAP1 exon 1-MAML2 fusion (4/5 lesions). YAP1-NUTM1 fusions were enriched in dermal duct tumors (2/2 lesions), poroid hidradenomas (4/6 lesions), porocarcinomas (6/11 lesions), poromas in the head and neck region (15/27 lesions), and poromas with necrotic foci (10/15 lesions). Because the number of each histological variant is rather limited in this study due to their rarity, further investigation based on a larger case series is desirable. However, it is notable that YAP1-NUTM1 fusions are enriched in porocarcinomas and poromas with primarily dermal localization, implying the link between the specific fusions and growth patterns. Examination of other skin tumors, including 24 squamous cell carcinomas, 32 basal cell carcinomas, 5 cutaneous adenocarcinomas, 9 Merkel cell carcinomas, and 27 seborrheic keratoses, did not identify any of the recurrent YAP1 fusions. These observations indicate that YAP1 fusions are highly recurrent and specific to poromas and porocarcinomas among skin neoplasms.

Considering that YAP1 and MAML2 are on the opposite strands of adjacent genetic loci on chromosome 11p, the frequent coexpression of YAPI-MAML2 and MAML2-YAP1 fusion transcripts is thought to be the consequence of intrachromosomal inversions (Supplemental Figure 3). Since NUTM1 and WWTR1 are on chromosome 15q14 and 3q25, respectively, the YAP1-NUTM1 and WWTR1-NUTM1 fusions are expected to result from interchromosomal translocations. Fluorescence in situ hybridization analysis revealed the YAP1 locus rearrangement in 104 poromas, including those analyzed by RNA sequencing, for the presence of the fusions detected by next-generation sequencing and possible fusion transcripts predicted from the exon structures of YAPI, MAML2, and NUTM1 (Supplemental Table 2). RT-PCR followed by Sanger sequencing detected YAPI-MAML2, MAML2-YAP1, YAPI-NUTM1, and WWTR1-NUTM1 fusions in 71, 48, 21, and 1 poromas, respectively (Figure 1A and B). Furthermore, an examination of 11 porocarcinomas identified YAPI-MAML2 and YAPI-NUTM1 fusions in 1 and 6 lesions, respectively. All the lesions with MAML2-YAP1 fusions concurrently expressed the reciprocal YAPI-MAML2 fusions; conversely, 48 of 71 (67.6%) YAPI-MAML2-positive lesions expressed MAML2-YAP1 fusions. The YAPI-NUTM1 and WWTR1-NUTM1 fusions were mutually exclusive with others. Multiple variant transcripts were detected for YAPI-MAML2, MAML2-YAP1, and YAPI-NUTM1, often in single tumors. All the fusion transcripts were in-frame. Collectively, YAPI fusions were expressed in 92 poromas (88.5%) and 7 porocarcinomas (63.6%), and 1 poroma was associated with a WWTR1 fusion (1.0%). The common presence of YAPI fusions in poromas and porocarcinomas supports their histogenetic relationship, which is consistent with the idea that a significant proportion of porocarcinomas develop through the malignant transformation of preexisting poromas (2, 9, 11). To our knowledge, among the identified YAPI and WWTR1 fusions, only a YAPI-MAML2 fusion was previously reported in a single case of nasopharyngeal carcinoma (14), whereas the other fusion transcripts have not been previously described.
portion expression in 100 poromas (96.2%) and 7 porocarcinomas (63.6%), including all the lesions with the YAP1 fusions (Figure 2 and Figure 3). The discrepant expression of the N- and C-terminal portions of YAP1 is consistent with the presence of YAP1-MAML2 or YAP1-NUTM1 fusion products. At the same time, it suggests the absence of MAML2-YAP1 fusion products. Seven poromas showed the discordant expression of N- and C-terminal regions of YAP1 in the absence of YAP1 fusion transcripts. We expect that these lesions might also have different types of YAP1 fusions, but the limitation in sample quality due to the use of formalin-fixed paraffin-embedded specimens precluded further investigation of other fusions in these lesions. The lesion with the WWTR1-NUTM1 fusion was also diffusely positive for the YAP1 N-terminus antibody, likely reflecting the known cross-reactivity of the antibody with the N-terminal portion of WWTR1 (16). Expression of NUTM1, also known as NUT, was observed in 25 poromas (24.0%) and 6 porocarcinomas (54.5%), including all lesions with the YAP1-NUTM1 fusions.

YAP1 immunohistochemistry on other skin tumors, including 23 squamous cell carcinomas, 24 basal cell carcinomas, 5 cutaneous adenoacanthomas, 9 Merkel cell carcinomas, and 26 seborrheic keratoses, showed common expression of YAP1, in agreement with previous reports (17, 18). However, in contrast to poromas and porocarcinomas, the expression patterns of the N- and C-terminal regions of YAP1 were consistently identical in the respective tumors, consistent with the WT protein expression. Also, they exhibited cytoplasmic in addition to nuclear expression of YAP1, unlike poromas and porocarcinomas. Thus, our immunohistochemical analysis could easily distinguish YAP1-MAML2 and YAP1-NUTM1 fusion products from the WT YAP1 based on the discordant expression of the N- and C-terminal regions of YAP1. Additionally, NUTM1 expression was never observed in skin tumors other than poromas and porocarcino-

Although there were some differences in the prevalence of respective fusion types, YAP1 fusions were frequently detected in both poromas and porocarcinomas. Therefore, we wanted to find out if any genetic alterations were involved in the malignant transformation of poroid neoplasms. To address this issue, we analyzed 23 poromas and 9 porocarcinomas using the NCC oncpanel test, a next-generation sequencing panel targeting 114 cancer-associated genes (15). The analysis identified a total of 49 protein-altering mutations (Supplemental Table 4 and Supplemental Table 5). Porocarcinomas tended to harbor a larger number of mutations than poromas (average 3.0 vs. 0.96 mutations/lesion). However, only 3 genes were recurrently mutated in porocarcinomas: KRAS, SETD2, and TP53. Each of these genes was mutated in only 2 of the lesions and SETD2 and TP53 mutations were also detected in poromas. These results indicate that mutations in major cancer-related genes cannot be used to distinguish benign and malignant poroid neoplasms.

To examine the expression of fusion protein products in clinical specimens, we performed immunohistochemical staining using 2 antibodies against YAP1. The analysis revealed the diffuse nuclear expression of the N-terminal portion and the absence of C-terminal portion expression in 100 poromas (96.2%) and 7 porocarcinomas (63.6%), including all the lesions with the YAP1 fusions (Figure 2 and Figure 3). The discrepant expression of the N- and C-terminal portions of YAP1 is consistent with the presence of YAP1-MAML2 or YAP1-NUTM1 fusion products. At the same time, it suggests the absence of MAML2-YAP1 fusion products. Seven poromas showed the discordant expression of N- and C-terminal regions of YAP1 in the absence of YAP1 fusion transcripts. We expect that these lesions might also have different types of YAP1 fusions, but the limitation in sample quality due to the use of formalin-fixed paraffin-embedded specimens precluded further investigation of other fusions in these lesions. The lesion with the WWTR1-NUTM1 fusion was also diffusely positive for the YAP1 N-terminus antibody, likely reflecting the known cross-reactivity of the antibody with the N-terminal portion of WWTR1 (16). Expression of NUTM1, also known as NUT, was observed in 25 poromas (24.0%) and 6 porocarcinomas (54.5%), including all lesions with the YAPI-NUTM1 fusions.

YAP1 immunohistochemistry on other skin tumors, including 23 squamous cell carcinomas, 24 basal cell carcinomas, 5 cutaneous adenoacanthomas, 9 Merkel cell carcinomas, and 26 seborrheic keratoses, showed common expression of YAP1, in agreement with previous reports (17, 18). However, in contrast to poromas and porocarcinomas, the expression patterns of the N- and C-terminal regions of YAP1 were consistently identical in the respective tumors, consistent with the WT protein expression. Also, they exhibited cytoplasmic in addition to nuclear expression of YAP1, unlike poromas and porocarcinomas. Thus, our immunohistochemical analysis could readily distinguish YAP1-MAML2 and YAP1-NUTM1 fusion products from the WT YAP1 based on the discordant expression of the N- and C-terminal regions of YAP1. Additionally, NUTM1 expression was never observed in skin tumors other than poromas and porocarcino-

Figure 2. Expression of YAP1 and NUTM1 in poromas, a porocarcinoma, and a squamous cell carcinoma. Tumors with YAP1 fusions showed diffuse nuclear expression of the N-terminal region of YAP1 but lacked the expression of the C-terminal region. Squamous cell carcinoma showed nuclear and cytoplasmic staining with both N- and C-terminus antibodies. The diffuse nuclear expression of NUTM1 was exclusively observed in tumors with the YAP1-NUTM1 fusions. The anti-YAP1 N-terminus antibody, but not the C-terminus antibody, cross-reacts with the WWTR1. Scale bar: 100 μm.
mas, indicating its specificity for NUTM1 fusion-positive poromas and porocarcinomas among skin tumors. Taken together, YAP1 and WWTR1 fusions were exclusive to poromas and porocarcinomas among skin tumors, and thus the detection of these fusion transcripts or protein products would have diagnostic applications.

The identification of a WWTR1 fusion in a single lesion of poroma, in addition to frequent YAP1 fusions, is remarkable because both YAP1 and WWTR1, also known as YAP and TAZ, respectively, encode paralogous transcriptional regulators of TEAD (19, 20). Activation of YAP1/WWTR1 is widely observed in various tumorigenic processes and plays roles in stemness, proliferation, invasion, and chemoresistance (19, 21). Physiologically, the activity of YAP1/WWTR1 is negatively regulated by the Hippo signaling pathway. Inactivating mutations of Hippo pathway components, leading to aberrant activation of YAP1/WWTR1, have been reported in various cancers, supporting the tumor suppressive function of this pathway (19, 20). Recurrent genetic alterations of YAP1 and WWTR1 themselves have only been reported in epithelioid hemangioendothelioma (22–24). More than 90% of epithelioid hemangioendotheliomas have WWTR1-CAMTA1 fusions and most of the remaining cases express a YAP1-TFE3 fusion. The WWTR1-CAMTA1 fusion protein shows constitutive nuclear localization, dysregulated TEAD activation, and transforming activity (25). Notably, similar to these previously reported WWTR1 fusions, the putative YAP1-MAML2, YAP1-NUTM1, and WWTR1-NUTM1 fusion products retain TEAD-binding domains derived from YAP1 or WWTR1 (Figure 4A).

MAML2 constitutes the 3’ part of CRTC1-MAML2 fusions, which is common in mucoepidermoid carcinoma of the salivary gland, and the interaction between p300 and the MAML2-derived transactivation domain is critical for their transforming activity (26, 27). The NUTM1-derived portion of YAP1-NUTM1 fusions also constitutes other tumor-related fusion proteins, including BRD4-NUTM1 in NUT midline carcinoma and CIC-NUTM1 in central nervous system Ewing sarcoma family tumor (28–30), and the recruitment of CBP and p300 is required for the oncogenic property of the BRD4-NUTM1 fusion (29). Thus, all the YAPI and WWTR1 fusions detected in poromas and porocarcinomas harbor the N-terminal TEAD-binding domain of YAP1 or WWTR1 (31), and the MAML2- or NUTM1-derived regions that interact with transcriptional coactivators, CBP and p300 (27, 29). Based on the common presence of domains to interact with transcription factors and transcriptional cofactors across these fusions, we postulated that these fusions function as a potent transcriptional activator of TEAD. In contrast, MAML2-YAP1 fusions lack these domains.

To test the functional significance of the YAP1 fusions, we first examined the intracellular localization of the YAP1 products in HEK293T cells. Normally, active Hippo pathway signaling leads to the cytoplasmic retention and degradation of YAP1, inhibiting the formation of a complex with TEAD transcription factors (19, 20). WT YAP1 and a constitutively active mutant, YAP1S127A, were distributed in both the nucleus and cytoplasm (Figure 4B). In contrast, YAP1-MAML2 and YAP1-NUTM1 fusions exhibited constitutive nuclear localization, dysregulated TEAD activation, and transforming activity (25). Notably, similar to these previously reported WWTR1 fusions, the putative YAP1-MAML2, YAP1-NUTM1, and WWTR1-NUTM1 fusion products retain TEAD-binding domains derived from YAP1 or WWTR1 (Figure 4A).
concentration of TEAD transcription factors and their transforming activity. Although two-thirds of YAP1-MAML2 fusions were associated with the reciprocal MAML2-YAP1 fusions, functional assays showed the lack of their transforming activity, and immunohistochemical study failed to detect their protein products. Thus, MAML2-YAP1 fusions are likely nonfunctional by-products of YAP1-MAML2 fusions, resulting from intrachromosomal inversion.

Next, we tested if YAP1 and WWTR1 fusions also show transforming activity in epithelial cells by using an immortalized human dermal keratinocyte (HDK) cell line (33). A reporter assay was performed by using doxycycline-dependent inducible cell lines stably transduced with a TEAD reporter (Supplemental Figure 5A), because of the low transfection efficiency of the HDK cells. As of triple reporter assays on HEK293T cells transfected with doxycycline-inducible vectors. YAP1S127A and YAP1S145A represent constitutively active mutants. The luciferase activity of EGFP-transfected cells in the absence of doxycycline was set at 1 to indicate relative luciferase activities. Data represent mean of triplicate measurements ± SD. (D) Soft agar colony formation assay of NIH3T3 cells expressing the fusion transgenes. NIH3T3 cells were transduced with doxycycline-inducible retrovirus vectors to express the respective transgenes and subjected to a soft agar colony formation assay in the presence of doxycycline. None of the clones formed colonies in the absence of doxycycline. Scale bar: 200 μm.

Figure 4. Functional significance of YAP1 and WWTR1 fusions. (A) Structures of the putative fusion gene products expressed in poromas and porocarcinomas. Arrows indicate fusion breakpoints. Notice that YAP1-MAML2, YAP1-NUTM1, and WWTR1-NUTM1 fusion gene products harbor a TEAD-binding domain derived from YAP1 or WWTR1 and a p300-binding domain derived from MAML2 or NUTM1. (B) Intracellular localization of YAP1 fusion gene products. The FLAG-tagged proteins were detected by immunofluorescence staining with nuclear staining using DAPI. Scale bars: 10 μm. (C) TEAD luciferase reporter assays on HEK293T cells transfected with doxycycline-inducible vectors. YAP1S127A and YAP1S145A represent constitutively active mutants. The luciferase activity of EGFP-transfected cells in the absence of doxycycline was set at 1 to indicate relative luciferase activities. Data represent mean of triplicate measurements ± SD. (D) Soft agar colony formation assay of NIH3T3 cells expressing the fusion transgenes. observed with NIH3T3 cells, expression of YAP1-MAML2, YAP1-NUTM1, and WWTR1-NUTM1 fusions strongly upregulated the expression of the TEAD reporter (Supplemental Figure 5B). A soft agar colony formation assay showed enhanced anchorage-independent growth upon the induction of YAP1-MAML2, YAP1-NUTM1, and WWTR1-NUTM1 (Supplemental Figure 5C). However, these colonies were smaller than those formed by cells expressing constitutively active YAP1 and WWTR1 mutants. In addition, cells overexpressing WT YAP1 and WWTR1 also formed small colonies. These findings indicate that YAP1 and WWTR1 fusions activate TEAD transcription factors and also promote anchorage-independent growth in epithelial cells. However, they may exhibit somewhat different biological effects in different cell types. The present study identified highly recurrent YAP1 and WWTR1 fusions in poromas and porocarcinomas. The YAP1 and WWTR1 fusions are potent transcriptional activators of TEAD and have transforming activity. The respective fusion types are likely associated with several clinicopathologic features, including the enrichment of YAP1-NUTM1 fusions in porocarcinomas. Since YAP1 fusions are specific to poromas and porocarcinomas among skin tumors, the detection of their protein products would have immediate diagnostic applications. Furthermore, the identification of recurrent YAP1 fusions in porocarcinomas suggests YAP1-TEAD-dependent transcription as a potential therapeutic target against this rare malignancy.

**Methods**

Additional information is provided in Supplemental Methods.

**Study approval.** The study was approved by the Ethical Committee of National Cancer Center, Tokyo, Japan (approval 2017-078).

**Author contributions**

SS, TK, and TM contributed equally to this work. SS, TK, and TM designed the study. SS, ER, RO, HI, TM performed next-generation and Sanger sequencing. SS, SW, and TM performed histological, immunohistochemical, and FISH analyses. TK performed functional assays. KS, SA, KT, MI, YS, and NY provided tissue samples and clinical information. NG provided cDNA clones. SS wrote the manuscript with support from TK and TM.
