Abstract

Allergic asthma is mediated by T helper 2 (Th2) responses to inhaled allergens. Although previous experiments indicated that Notch signaling activates expression of the key Th2 transcription factor Gata3, it remains controversial how Notch promotes allergic airway inflammation. Here we show that T cell-specific Notch deficiency in mice prevented house dust mite-driven eosinophilic airway inflammation and significantly reduced Th2 cytokine production, serum IgE levels and airway hyperreactivity. However, transgenic Gata3 overexpression in Notch-deficient T cells only partially rescued this phenotype. We found that Notch signaling was not required for T cell proliferation or Th2 polarization. Instead, Notch-deficient in vitro polarized Th2 cells showed reduced accumulation in the lungs upon in vivo transfer and allergen challenge, as Notch-deficient Th2 cells were retained in the lung draining lymph nodes. Transcriptome analyses and sequential adoptive transfer experiments revealed that while Notch-deficient lymph node Th2 cells established competence for lung migration, they failed to upregulate the sphingosine 1-phosphate receptor (S1PR1) and its critical upstream transcriptional activator Krüppel-like factor 2 (KLF2). As this KLF2-S1PR1 axis represents the essential cell-intrinsic regulator of T cell lymph node egress, we conclude that the druggable Notch signaling pathway licenses the Th2 response in allergic airway inflammation via promoting lymph node egress.

Allergic asthma, Cytokines, Gata3, Lymph node egress, S1PR1, T cell migration, Notch signaling, RBPJκ, Th2 cell, Type-2 immunity
Introduction

Allergic asthma is a common but heterogeneous chronic inflammatory lung disease characterized by a type 2 airway inflammation and bronchial hyperreactivity (1). Asthma patients experience symptoms such as wheezing, shortness of breath and chest tightness, which are induced by various allergens including house dust mite, fungal spores, pollen and animal dander. While many asthma patients respond well to standard treatment with inhaled glucocorticoids and β2-agonists, a significant fraction of patients does not achieve disease control using these agents, resulting in high morbidity and symptom burden.

Upon allergen exposure, barrier epithelial cells in the lungs of susceptible individuals mount a pro-inflammatory response involving the secretion of chemokines, cytokines and alarmins that induce activation of group 2 innate lymphoid cells (ILC2s) and dendritic cells to mount a T helper 2 (Th2)-mediated immune response (2, 3). Disease hallmarks of allergic asthma can be attributed to cytokines that are produced by T helper 2 (Th2) cells: IL-4 induces IgE class-switching of B cells, IL-5 recruits eosinophils and IL-13 provokes smooth muscle hyperreactivity, goblet cell hyperplasia and mucus production (4). It is thought that IL-4 signaling via STAT6 is the main driver of Th2 cell differentiation via enhancing the expression of the key Th2 transcription factor Gata3 (5, 6) (reviewed in Ref. (7)). However, Gata3 and IL-4 can also be induced by Notch signaling, given the capacity of the downstream Notch effector recombination signal binding protein for immunoglobulin κ (RBPJκ) to bind to the upstream Gata3 promoter and a 3’ enhancer element of the Il4 gene (8-12).

The Notch signaling cascade is an important evolutionary conserved pathway critically involved in cell-cell communication and was originally identified as a pleiotropic regulator of cell fate during embryonic and adult life (reviewed in Ref. (13)). The function of the Notch pathway is highly context-dependent, as is illustrated by its crucial role at several stages of lymphocyte development, including the B/T, the αβ/γδ T cell and CD4/CD8 lineage choices (14-16). Because aberrant activity of the Notch pathway has been implicated in various malignancies, it represents an important target for cancer therapy (13). In mature peripheral CD4+ T cells Notch signaling is critical for Th2 responses, as was
shown in mice deficient for RBPJκ or both the Notch1 and Notch2 receptors as well as in mice expressing a dominant-negative form of the essential RBPJκ coactivator master-mind-like (MAML) (8, 10, 11, 17). Absence of Gata3 turned Notch from a Th2 inducer into potent driver of Th1 differentiation (10, 11). Pharmacological inhibition of Notch signaling using γ-secretase inhibitors (GSI) or the cell-permeable stapled peptide SAHM1, led to decreased Th2 cytokine production in allergic asthma or food allergy models (18-20). We recently found that surface expression of NOTCH1 and NOTCH2 on both circulating memory CD4+ T cells and Th2 cells is increased in patients with asthma compared to healthy controls (21). Hereby, NOTCH1+ memory CD4+ T cells displayed a more activated phenotype – characterized by increased expression of CD25/IL-2R and the prostaglandin DP2 receptor CRTH2 – than their NOTCH+ counterparts (21).

Several studies provided evidence that the Notch ligands Jagged and delta-like ligand (DLL) instruct Th2 and Th1 cell differentiation, respectively (8, 9). In contrast, an ‘unbiased amplifier’ model was proposed in which Notch ligands are not instructive but rather function to generally amplify both Th1, Th2 and Th17 cell responses by enhancing proliferation, cytokine production and survival (22, 23). Accordingly, we and others found that blocking Notch signaling only during the challenge phase of allergen exposure - and not during sensitization - led to decreased features of allergic airway inflammation (AAI) (18, 20). These findings support a role for Notch signaling in optimizing immune responses rather than inducing initial Th2 cell differentiation. Hence, the precise function of Notch signaling during Th2 cell differentiation and activation in vivo, especially in the context of allergic inflammatory disease, remains controversial.

Here, we employed a combination of flow cytometry, histology and transcriptome analyses of transgenic mice to dissect the role of Notch signals in T cells in acute and chronic models for house dust mite (HDM) driven AAI. These experiments revealed that a lack of Notch1/Notch2 expression on T cells prevents AAI, which could be only partially rescued by enforced Gata3 expression. While Notch signaling was not required for Th2 differentiation or proliferation, the absence of Notch signals caused
lymph node retention and impaired lung migration of Th2 cells, uncovering a novel role for Notch signals in the control of Th cell trafficking that explains how Notch signaling licenses AAI.
Results

Notch1 and Notch2 expression on CD4+ T cells is required for the induction of AAI

We crossed Notch1<sup>fl/fl</sup> and Notch2<sup>fl/fl</sup> mice, in which critical exons are flanked by loxP sites (14, 24), with CD4-Cre transgenic mice to delete Notch1 and Notch2 specifically in T cells. Consistent with published findings (25), T cell development in thymus and spleen from CD4-Cre transgenic Notch1<sup>fl/fl</sup>Notch2<sup>fl/fl</sup> mice was not affected (Supplemental Figure 1A-B).

We induced AAI in Notch1 and Notch2 single (N1<sup>ΔCD4/ΔCD4</sup> or N2<sup>ΔCD4/ΔCD4</sup>) and double-deficient (N1N2<sup>ΔCD4/ΔCD4</sup>) mice and wild-type (WT) littermates through sensitization and multiple challenges with HDM (Figure 1A). In these experiments, we included control groups of mice that were equally challenged with HDM, but that were sensitized with PBS. Analysis of broncho-alveolar lavage (BAL) fluid of WT mice four days after the last HDM challenge showed significantly increased absolute numbers of eosinophils, B cells, CD4+ T cells and dendritic cells (DCs) in HDM-sensitized mice, compared with PBS-sensitized mice (Figure 1B). N1<sup>ΔCD4/ΔCD4</sup> mice developed a milder form of AAI characterized by reduced eosinophilia, while HDM-sensitized N2<sup>ΔCD4/ΔCD4</sup> mice displayed an AAI similar to WT mice. Strikingly, BAL fluid from HDM-sensitized N1N2<sup>ΔCD4/ΔCD4</sup> mice did not show any increase in immune cell numbers (Figure 1B). The HDM-mediated increase in the total numbers of IL-4<sup>+</sup>, IL-5<sup>+</sup>, IL-13<sup>+</sup>, IL-9<sup>+</sup>, IL-17<sup>+</sup> and IFN-γ<sup>+</sup> CD4<sup>+</sup> T cells observed in WT animals was completely abolished in BAL fluid (Figure 1C) and lungs (data not shown) of N1N2<sup>ΔCD4/ΔCD4</sup> mice. Accordingly, Gata3 induction was severely impaired in CD4<sup>+</sup> T cells in the BAL fluid (Figure 1D-E), and lungs (data not shown) from N1N2<sup>ΔCD4/ΔCD4</sup> mice. Total numbers of RORγ<sup>+</sup> Th17 and FoxP3<sup>+</sup>CD25<sup>+</sup> Tregs were also reduced in the BAL fluid of N1N2<sup>ΔCD4/ΔCD4</sup> mice, compared to the other three groups of mice (Supplemental Figure 1C). HDM-restimulated MedLN cells from N1N2<sup>ΔCD4/ΔCD4</sup> mice showed severely reduced production of IL-5 and IL-13 (Figure 1F). We found reduced levels of HDM-specific as well as total IgG1 and IgE in the serum of N1N2<sup>ΔCD4/ΔCD4</sup> mice, compared to WT controls (Figure 1G, Supplemental Figure 1D). In these experiments, we noticed redundancy for Notch1 and Notch2, whereby Notch1 appeared dominant (Figure 1B-1G).
Follicular T helper (Tfh) cells promote type-2 immunity and have been postulated as precursors of HDM-specific Th2 cells (26, 27). Moreover, Tfh responses rely on Notch signaling (28, 29). Indeed, we observed fewer PD1+CXCR5+ Tfh cells in the MedLN of N1N2ΔCD4/ΔCD4 mice as compared to WT controls (Supplemental Figure 1E). To directly assess the importance of a Tfh response for HDM-driven AAI, we genetically deleted the Notch ligand DLL4 on CCL19+ lymph node fibroblastic reticular cells, which prevents the accumulation of Tfh cells in the MedLN (28) (Supplemental Figure 2A-C). Failure to induce Tfh cells indeed blunted IgE induction (for total serum IgE see Supplemental Figure 2D; HDM-specific IgE was detected in the serum of 6/7 WT mice but only in 2/7 DLL4ΔCCL19/ΔCCL19 animals). Strikingly, we still observed full-blown eosinophilia in Tfh-deficient DLL4ΔCCL19/ΔCCL19 mice and even higher numbers of Th2 cells in the BAL fluid than WT littermates (Supplemental Figure 2E-F). Therefore, the role of Notch signals in Tfh formation does not provide an explanation for our finding that eosinophilic HDM-driven AAI is reduced in the absence of Notch on T cells.

Together, these findings show that the induction of HDM-driven AAI is moderately reduced in N1ΔCD4/ΔCD4 mice, apparently normal in N2ΔCD4/ΔCD4 mice and abrogated in N1N2ΔCD4/ΔCD4 mice.

**Notch signaling in CD4+ T cells is required for airway remodeling and hyperreactivity**

To investigate whether Notch signaling is required for AAI-associated airway remodeling and hyperreactivity, we subjected N1N2ΔCD4/ΔCD4 and WT mice to a chronic HDM-induced asthma model in which mice were challenged with HDM for 5 consecutive weeks (Figure 2A). In line with our findings in the acute AAI model, we found reduced inflammation in BAL fluid of HDM-challenged N1N2ΔCD4/ΔCD4 mice as compared to WT controls (Figure 2B). Interestingly, the frequency of CD69+ tissue-resident memory CD4+ T cells in the lung was not affected by the absence of Notch signaling (Supplemental Figure 3A-B), although Th2-cytokine expressing CD4+ T cells were reduced in the lung and virtually absent in BAL fluid (Supplemental Figure 3C-D).

The presence of HDM-induced cellular infiltrates and collagen deposition in the lungs was reduced in HDM-treated N1N2ΔCD4/ΔCD4 mice, compared to WT mice (Figure 2C). In this chronic AAI
model (30), inducible bronchus-associated lymphoid tissues (iBALT) structures were formed that contained both T and B cells, including GL7+ germinal center (GC) B cells (Figure 2D). By contrast, in the lungs of HDM-exposed $N1N2^{ΔCD4/ΔCD4}$ mice, most T cells were not iBALT-associated and iBALT structures were less abundant, smaller in size and negative for GL7+ GC B cells (Figure 2D). IgM plasma cells were readily detectable in or close to the iBALT structures in WT mice, but not in $N1N2^{ΔCD4/ΔCD4}$ animals (Figure 2D).

Airway hyperreactivity, measured by resistance to methacholine, was significantly lower in HDM-treated $N1N2^{ΔCD4/ΔCD4}$ mice than in WT mice (Figure 2E). Likewise, both total and HDM-specific IgG1 and IgE serum levels were strongly decreased in HDM-challenged $N1N2^{ΔCD4/ΔCD4}$ mice (Figure 2F, Supplemental Figure 3E). The lack of IgE response in this chronic AAI model cannot be readily explained by a GC defect, since $N1N2^{ΔCD4/ΔCD4}$ mice displayed normal numbers of GL7+CD95+ GC B cells and Tfh cells in the MedLN, in contrast to our findings in the acute HDM-driven AAI model (compare Supplemental Figure 3F-G and Supplemental Figure 1E).

In the acute AAI model (Figure 1A), both PBS and HDM-sensitized mice were challenged with HDM, resulting in an equally high MedLN cellularity in both groups (data not shown). In the chronic AAI model however, we compared HDM-challenged mice with mice that had received only PBS for 5 weeks, so we could evaluate the induction of T cell expansion and activation in the MedLN. Despite the strongly reduced AAI in $N1N2^{ΔCD4/ΔCD4}$ mice, we observed a robust HDM-driven increase in MedLN cellularity and CD4+ T cell counts. Strikingly, Gata3+ Th2 cells and activated CD25+FoxP3- CD4+ T cells were particularly abundant in the MedLN of $N1N2^{ΔCD4/ΔCD4}$ mice (Figure 2G). In vitro HDM-restimulated MedLN cultures from $N1N2^{ΔCD4/ΔCD4}$ mice produced IL-13, although cytokine levels appeared lower than in cultures from WT mice (Figure 2H).

In summary, upon chronic HDM exposure, Notch signaling in CD4+ T cells is required for the induction of AAI, tissue remodeling and bronchial hyperreactivity in the lung. However, in the chronic HDM-driven AAI model Notch signaling does not appear to be critical for activation of naïve T cells and
Th2 polarization in the MedLN, but rather for aspects of memory Th2 cell function, such as the maintenance of their Th2 identity or their migration to the lungs.

**Enforced Gata3 expression only partially rescues AAI induction in N1N2ΔCD4/ΔCD4 mice**

Because Gata3 is crucial for Th2 cell identity and is a direct Notch target (8) we investigated whether enforced Gata3 expression could rescue AAI induction in the absence of Notch signaling. We employed transgenic (Tg) CD2-Gata3 mice, which constitutively express Gata3 in all T cell subsets under the control of the human CD2 promoter and show increased AAI susceptibility (31, 32). We investigated CD2-Gata3 Tg and non-Tg littermates that were N1ΔCD4/ΔCD4, N1N2ΔCD4/ΔCD4 or WT in our acute HDM-driven AAI model. Whereas enforced Gata3 expression increased the numbers of various inflammatory cells in BAL fluid of all three groups upon HDM exposure, eosinophilia was only partially rescued in CD2-Gata3 N1N2ΔCD4/ΔCD4 mice (Figure 3A, Supplemental Figure 4A). Similarly, mucus hyperproduction by goblet cells (as quantified by histological PAS staining) was only partially rescued in CD2-Gata3 N1ΔCD4/ΔCD4 and CD2-Gata3 N1N2ΔCD4/ΔCD4 mice compared with non-transgenic littermates (Figure 3B-C). Importantly, enforced Gata3 expression increased the numbers of IL-5+, IL-13+ and Gata3+ CD4+ T cells in BAL fluid of WT and N1ΔCD4/ΔCD4 mice, but did not induce any recovery of cytokine-producing Th2 cells in the BAL fluid of N1N2ΔCD4/ΔCD4 mice (Figure 3D-F, Supplemental Figure 4B). In contrast, the CD2-Gata3 Tg did rescue IL-9+ CD4+ T cell, RORγ+ Th17 and FoxP3+CD25+ Treg numbers in BAL fluid (Supplemental Figure 4B). IFNγ+ CD4+ T cells were unaffected, as expected. Enforced Gata3 expression did not affect HDM-specific or total serum IgG1 levels. However, transgenic Gata3 enhanced the induction of both HDM-specific and total serum IgE in WT and N1ΔCD4/ΔCD4 mice, but not in N1N2ΔCD4/ΔCD4 mice (Figure 3G, Supplemental Figure 4C). Finally, we also observed that enforced Gata3 expression in mice with a T-cell specific deficiency of RBPJκ did not rescue hallmarks of the Th2 response, including induction of eosinophilia and IL-4+, IL-5+ and IL-13+ Th cells in BAL fluid as well as serum IgE serum (Supplemental Figure 4D-F).
In summary, although enforced Gata3 expression largely rescued AAI induction in N1ΔCD4/ΔCD4 mice, it had limited effects in mice with T cells lacking both Notch1 and Notch2 or RBPJκ. These findings indicate that in type 2 responses, Notch has additional critical functions in CD4+ T cell biology beyond Gata3 induction.

**Notch signals are not required for activation, proliferation and Th2 differentiation of CD4+ T cells**

To further explore the capacity of Notch-deficient CD4+ T cells to differentiate into the Th2 lineage, we crossed N1N2ΔCD4/ΔCD4 mice with OTII transgenic mice expressing a chicken ovalbumin (OVA)-specific T cell receptor (TCR) on CD4+ T cells. Purified CFSE-labeled naïve CD4+ T cells from OTII WT and OTII N1N2ΔCD4/ΔCD4 mice were co-cultured with bone marrow-derived GM-CSF DCs (maturated with HDM or LPS and loaded with a range of OVA concentrations). A lack of Notch signaling in the OTII CD4+ T cells did not hamper their proliferation or activation (as indicated by surface CD44 expression) (Figure 4A; Supplemental Figure 5A). Moreover, induction of Gata3 and the capacity to produce IL-4 or IL-13 were not affected (Figure 4B-C). Rather, a modest increase in Gata3 expression and cytokine production was noticed, particularly at lower antigen concentrations. Likewise, *in vitro* activation and polarization of purified naïve T cells from RBPJκΔCD4/ΔCD4 and WT mice using anti-CD3/CD28 antibodies in combination with various cytokines and anti-cytokine antibody cocktails (33) did not affect cellular expansion or Th subset differentiation (Supplemental Figure 5B-E).

Notch signaling was reported to potentiate phosphatidylinositol 3-kinase (PI3K)-dependent signaling downstream of the TCR and CD28 through activation of Akt kinase and mammalian target of rapamycin (mTOR) (34-36). Notch could in this way enhance T cell effector function and survival, enabling T cells to respond to lower antigen doses. However, we did not detect any defect in the phosphorylation of the S6 ribosomal protein, a downstream target of Akt, in splenic T cells from N1N2ΔCD4/ΔCD4 mice stimulated for 3 hours with a range of anti-CD3/CD28 antibody concentrations (Supplemental Figure 5F).
Next, we investigated if Notch signaling is required for activation of naïve T cells \textit{in vivo}. CFSE-labeled OTII T cells from $N1N2^{\Delta CD4/\Delta CD4}$ and WT mice were injected intravenously into WT recipients. One day later, mice were challenged intranasally with OVA and/or HDM. Three days post-challenge, $N1N2^{\Delta CD4/\Delta CD4}$ and WT OTII T cells from MedLNs showed similar \textit{in vivo} proliferation or capacity to produce IL-4 (Figure 4D-E).

We conclude from these \textit{in vitro} and \textit{in vivo} experiments that Notch signaling is not critically involved in the expansion, activation or Th2 polarization of naïve CD4$^+$ T cells upon TCR stimulation.

\textbf{Notch signaling promotes lymph node egress of \textit{in vitro} polarized Th2 cells}

To explore the role of Notch in established Th2 cells, we transferred \textit{in vitro} polarized WT and $N1N2^{\Delta CD4/\Delta CD4}$ OTII CD4$^+$ T cells intravenously into WT recipient mice that were subsequently challenged with OVA and HDM for four consecutive days. On day 5, mice that received $N1N2^{\Delta CD4/\Delta CD4}$ Th2 cells had similar total cell counts in MedLNs, but a significantly reduced cellular influx into the lungs compared to mice that received WT Th2 cells (Figure 5A). Importantly, mice that received $N1N2^{\Delta CD4/\Delta CD4}$ OTII CD4$^+$ T cells had lower numbers of these cells in lungs, but significantly higher numbers in MedLNs (Figure 5B). Notch-deficient OTII CD4$^+$ T cells producing IL-4 and particularly IL-13 were reduced in the lungs, while proportions and absolute numbers of IL-4$^+$ or IL-13$^+$ cells in the MedLN were higher for $N1N2^{\Delta CD4/\Delta CD4}$ than for WT OTII CD4$^+$ T cells (Figure 5C; Supplemental Figure 5G). Moreover, substantially more $N1N2^{\Delta CD4/\Delta CD4}$ than WT OTII cells in the MedLN were positive for the CD44 memory marker, while proliferation rates were unaffected by Notch signals (Figure 5D-E).

Taken together, these findings support a role for Notch signaling in promoting the migration of memory Th2 cells from the lymph node into the lungs in the context of AAI.
Notch signals control a cytokine signaling gene expression program in Th2 cells in vivo

Next, we used RNA sequencing (RNA-Seq) to compare the transcriptomes of WT and N1N2ΔCD4/ΔCD4 OTII Th2 cells directly after in vitro polarization and 5 days after in vivo transfer and OVA/HDM-treatment. RNA-Seq confirmed defective expression of Notch1 and Notch2 in N1N2ΔCD4/ΔCD4 OTII Th2 cells (Supplemental Figure 6A). Principal component analysis (PCA) and unbiased hierarchical clustering of gene expression values revealed a negligible impact of Notch deficiency in vitro, while the transcriptomes of in vivo transferred WT and N1N2ΔCD4/ΔCD4 OTII Th2 cells isolated from MedLNs diverged substantially (Figure 6A, Supplemental Figure 6B), demonstrating that changes resulting from Notch deficiency arose following allergen challenge in vivo. While only 19 differentially expressed (DE) genes (defined as 2-fold up or downregulated, adjusted P<0.05) were detected after in vitro polarization, 681 genes differed between WT and N1N2ΔCD4/ΔCD4 OTII Th2 cells in the MedLN (Figure 6B-C, Supplemental Figure 6C-D, Supplemental Table 2). Pathway enrichment analyses of these 681 DE genes revealed a strong overrepresentation of genes involved in cytokine/chemokine production and responsiveness, as well as leukocyte chemotaxis and migration (Figure 6D).

As expected, MedLN N1N2ΔCD4/ΔCD4 OTII Th2 cells expressed dramatically reduced levels of the canonical Notch target gene Dtx1 (Supplemental Figure 6E-F). Many promoters of DE genes harbored RBPJκ DNA binding motifs (~36%, Figure 6E). While Il4 and Gata3 were reduced, Foxp3 and Rorg expression was unchanged (Figure 6F, Supplemental Figure 6F). Tbx21 (encoding T-bet) and Ifng were upregulated, suggesting diminished Th2 phenotypic stability and increased plasticity towards a Th1 phenotype in the absence of Notch (Figure 6F). Impaired Notch signaling in Th2 cells decreased the expression of genes associated with Th2 superenhancers, which are enriched for lineage-defining Th2 genes including Il4, Satb1 and Maf (37) (Figure 6E, Supplemental Table 2), as well as genes linked to asthma-associated genetic variants from genome-wide association studies (38), e.g. TLR1, SPP1 and PLCL1 (Figure 6E, Supplemental Table 2).

In summary, we found that Notch signaling regulates a critical part of the in vivo gene expression program that controls lymph node Th2 lineage identity and cytokine signaling.
Disruption of the KLF2-S1PR1 axis in Notch-deficient T cells

The most striking transcriptional changes in MedLN \(N1N2^{ΔCD4/ΔCD4}\) OTII Th2 cells concerned genes involved in cellular migration and chemotaxis (Figure 7A-B). Chemokine receptors associated with lung migration, including \(Ccr8\) (39), \(Cx3cr1\) (40) and \(Cxc3\) (41) were prominently upregulated in \(N1N2^{ΔCD4/ΔCD4}\) MedLN Th2 cells. Together with high-level expression of the Th2 lung homing marker \(Ccr4\) (42), this indicated that MedLN Notch-deficient Th2 cells adopted a phenotype that supports lung migration (Figure 7B). Flow cytometry analysis confirmed increased surface expression of CCR8 and CXCR3 on MedLN \(N1N2^{ΔCD4/ΔCD4}\) Th2 cells as compared to WT Th2 cells, reaching levels that were similar to or higher than those observed on lung Th2 cells, respectively (Figure 7C). In support of a functional lung migratory phenotype of \(N1N2^{ΔCD4/ΔCD4}\) MedLN OTII Th2 cells, PCA using expression values of the 681 DE genes clustered \(N1N2^{ΔCD4/ΔCD4}\) MedLN Th2 cells together with BAL fluid but not with MedLN WT Gata3\(^+\) Th2 cells (PC2, Figure 7D) from mice subjected to the more physiological acute HDM-driven AAI protocol depicted in Figure 1A. Indeed, critical T cell migration genes, \(Ccr6\), \(Cxc3\) and \(Sell\), showed similar transcriptional changes upon lung migration and when retained in the MedLN as Notch-deficient cells (Figure 7E).

Alternative explanations for the lung migratory defect we observed in Notch-deficient Th2 cells are persistent MedLN retention (43) and a failure to actively egress from the MedLN via sphingosine-1-phosphate (S1P) signaling (44). However, lymph node retention receptor genes \(Sell\) (encoding L-selectin) and \(Ccr7\), as well as \(Adrb2\) encoding the β2-adrenergic receptor that inhibits LN egress (45), were downregulated in \(N1N2^{ΔCD4/ΔCD4}\) MedLN Th2 cells (Figure 7B). Instead, \(N1N2^{ΔCD4/ΔCD4}\) MedLN Th2 cells exhibited reduced expression of \(S1pr1\) encoding the S1P receptor, the master T cell-intrinsic regulator of effector T cell lymph node egress (46), as well as its critical upstream regulator \(Klf2\) (47) (Figure 7B). \(Ecm1\), \(Foxo1\) and \(Cd69\), all implicated in regulation of S1PR1 expression (48, 49), were unchanged (Supplemental Figure 6F). \(Zfp36\), a negative regulator of \(Klf2\) in B cells (50) was downregulated. Direct control of \(Klf2\) expression by Notch signaling was further supported by extensive
RBPJκ binding of the Klf2 locus (including the promoter region, Figure 7F) in a T cell line (51). Transmigration of S1PR1-expressing T cells into lymphatic sinuses and subsequent egress into efferent lymph is mediated by an S1P gradient across lymphoid endothelial cells (LECs) (52). As it is conceivable that S1PR1 expression in T cells is induced by engagement of Notch receptors on LECs, we used RT-PCR to analyze expression of Notch ligand genes in sorted gp38+CD31+ LECs from WT mice three days after treatment with PBS or a single high dose of HDM. In vivo HDM exposure induced transcription of Jag1, Dll1 and Dll4 in LECs at levels that were comparable to those found in gp38+CD31+ fibroblastic reticular cells and DCs (Figure 7G).

Our findings strongly support disruption of the KLF2-S1PR1 axis - and not altered CCR7, L-selectin or β2AR expression - as the underlying cause of defective Th2 cell lymph node egress. Although Notch-deficient MedLN Th2 cells readily adopt a lung migratory phenotype, impaired MedLN egress prevents efficient lung migration, thus explaining the attenuated allergen-driven AAI in N1N2ΔCD4/ΔCD4 mice.

**Lymph node N1N2ΔCD4/ΔCD4 Th2 cells have substantial capacity to migrate into the lungs**

Next, we investigated whether the lung migratory phenotype of MedLN N1N2ΔCD4/ΔCD4 Th2 cells would indeed enable them to home towards the lung after adoptive transfer (and MedLN egress would thus no longer be required). To this end, we first transferred either WT or N1N2ΔCD4/ΔCD4 in vitro polarized OTII Th2 cells into WT recipient mice, which were subsequently challenged with OVA and HDM for four consecutive days (Figure 8A). Total CD4+ T cell fractions were isolated from the MedLNs of these mice, APC-labelled and adoptively transferred into a second group of WT mice that were treated with OVA and HDM one day prior to transfer (Figure 8A). In these experiments, the numbers of APC-labeled total CD4+ T cells or TCRVβ5+TCRVα2+ OT-II T cells that migrated into the spleen was comparable between the two groups of mice (Figure 8B). APC-labeled CD4+ T cells could not be retrieved from the lungs of mice that had received CD4+ T cells from MedLNs containing WT OTII Th2 cells. By contrast, in lungs of mice that had received CD4+ T cells from MedLNs containing N1N2ΔCD4/ΔCD4 OTII Th2 cells, a
population of APC-labeled CD4+ T cells was present that almost entirely consisted of $N1N2^{ΔCD4/ΔCD4}$ TCRβ5⁺TCRα2⁺ OT-II T cells (Figure 8C). In these mice, the fraction of APC-labeled CD4+ T cells migrating to the MedLN largely contained WT non-OTII CD4+ T cells and only very few $N1N2^{ΔCD4/ΔCD4}$ TCRβ5⁺TCRα2⁺ OT-II T cells. Thus, lymph node-derived Notch-deficient but not WT OTII Th2 cells were biased towards lung migration (Figure 8D).

Taken together, our findings demonstrate that Notch signaling is required for upregulation of the KLF2-S1PR1 axis, allowing antigen-activated Th2 cells to leave the lymph node and migrate into the lungs (Figure 8E).
Discussion

The Notch signaling pathway in T cells is essential for type 2 immune responses such as host defense to helminth infection but also allergic inflammation (8). However, it has remained obscure how Notch signaling supports Th2 cell-driven inflammation in vivo and whether Notch acts in an instructive or more unbiased fashion to shape CD4+ T cell fate.

We addressed the contested role of Notch signaling using a physiologically relevant HDM-driven mouse model of AAI. While the Notch1/2 receptors were indispensable for induction of eosinophilia, Th2 cell accumulation in the lungs, airway remodeling and HDM-specific IgE, rescue of these hallmarks of AAI by Gata3 overexpression was surprisingly limited. Notch signaling therefore controls critical aspects of Th2-mediated AAI beyond direct transcriptional activation of Gata3. We found that Notch1/2 or RBPJκ were not required for T cell activation, proliferation and Th2 polarization, both in vitro induced by anti-CD3/CD28 stimulation or antigen-loaded GM-CSF bmDCs, and in vivo through antigenic stimulation of transferred OVA-specific CD4+ T cells. Moreover, when in vitro differentiated OVA-specific Notch1/2-deficient Th2 cells were transferred into mice and activated by OVA, these cells showed apparently normal proliferation and Th2 cytokine production. Instead, Notch1/2-deficient Th2 cells displayed defective lung trafficking and accumulated in lung draining lymph nodes. These Notch1/2-deficient Th2 cells failed to upregulate the KLF2-S1PR1 axis, the essential mediator of lymph node egress. Nevertheless, their chemokine receptor expression signature enabled them to migrate into the lung, when the need for MedLN egress was removed via sequential adoptive transfer. Therefore, we conclude that Notch signals license the Th2 response in AAI via promoting lymph node egress (Figure 8E).

When T cells encounter antigen presented by activated DCs in the lymph node, KLF2 and S1PR1 expression is downregulated by TCR and IL-2R signaling (44). As a result, T cells are retained in the lymph node, allowing for sufficient time to interact with DCs. Only when polarized, Th2 cells prepare for emigration and upregulate the expression of ECM-1, which leads to inhibition of IL-2R signaling, KLF2/S1PR1 re-expression and Th2 cell egress (48). It is conceivable that the observed reduced Klf2 and S1pr1 expression in Notch1/2-deficient Th2 cells reflects an early activation arrest in
the lymph node prior to reaching the stage of egress competency. However, several lines of evidence support the alternative explanation that Notch signaling directly activates Klf2 and its target S1pr1. First, ECM-1 expression levels were not affected in Notch-deficient Th2 cells, indicating that the cells do reach the stage of ECM-1 upregulation. Second, RBPJκ binding of the Klf2 promoter region in a T cell line (51) is consistent with direct control of Klf2 expression by Notch signals. Thirdly, despite low S1PR1 expression, Notch-deficient Th2 cells are competent for lung migration and their transcriptional profile and chemokine receptor expression pattern showed a striking resemblance to Th2 cells in the airways. This transcriptomic similarity also makes it unlikely that reduced Klf2 expression or S1PR1 signaling would directly affect chemokine receptor expression in Th2 cells. In this context, it has been demonstrated that even in the absence of retention signals such as CCR7, cell-intrinsic S1PR1 signaling is the overriding factor that regulates effector T-cell egress kinetics from draining lymph nodes (46).

Our findings do not support a role for Notch in other pathways that can influence S1PR1 expression, including PI3K/mTOR signaling, CD69-mediated inhibition or transcriptional regulation via Foxo1. Importantly, our transcriptome analyses indicated no reinforced lymph node retention signals in Notch-deficient effector Th2 cells, because CCR7, L-selectin and β2AR expression levels were strongly downregulated. Nevertheless, it is evident that Notch signaling has additional effects, including direct regulation of Il4 and Gata3 gene expression (8). Accordingly, we found that Notch-deficient Th2 cells presented distinct cytokine (receptor) gene expression profiles and hallmarks of lineage instability, including a partial loss of repression of Th1 signature genes.

It is currently unknown which cells in the draining lymph node provide the signals that activate the Notch pathway in differentiated Th2 effector cells to support their egress. Prior to emigration, antigen-specific effector T cells localize adjacent to both cortical and medullary sinuses in the lymph node periphery, where they exhibit intense probing behavior with lymphatic endothelial cells before entering the sinuses in an S1PR1-dependent fashion (46). Therefore, it is attractive to speculate that endothelial cells are critical to provide Notch ligands, particularly since these cells have the capacity to upregulate Jagged expression in response to inflammatory mediators such as TNF and IL-6 (53, 54).
Accordingly, we found that HDM exposure in mice induced Jagged and Delta-like ligand expression in MedLN endothelial cells (Figure 7G) and that Jagged expression on DCs is not critical for HDM-driven allergic AAI in vivo (55).

It was recently shown in a helminth infection model that the Notch1/2 receptors on T cells are required for Tfh generation and IgE class switching, but largely dispensable for Th2 differentiation and lung eosinophilia (29). These results are in apparent contrast with our findings for AAI, as the absence of Notch signaling in T cells – irrespective of a successful Tfh response in the lymph node – abolished both IgE induction and lung eosinophilia. Directly comparing the two models is challenging, because of considerable differences in the immunopathological mechanisms involved. For example, cardinal features of the type-2 immune response, including IL-5/IL-13 production and eosinophilia, are rapidly induced by ILC2s in the Nippostrongylus brasiliensis model, which in turn support T cell activation (56).

In our HDM-driven AAI model, however, ILC2 induction relies on T cell activation (57) and on Notch signaling in T cells (see Figure 2B). Nevertheless, our experiments show that in HDM-driven AAI, a vigorous Th2 response is generated in the lung even in DLL4ΔCCL19/ΔCCL19 mice defective for MedLN Tfh responses. These data are in line with our previous findings in Cd40l−/− mice, in which eosinophilic airway inflammation in the chronic HDM-driven model is not hampered despite impaired Tfh cell generation (30). The role of Notch signals in Tfh formation therefore does not provide an explanation for our finding that eosinophilic AAI is reduced in the absence of Notch on T cells. Importantly, taken together the studies show that eosinophilia and lung Th2 responses in both helminth and HDM-driven experimental models appear independent of a Tfh response in draining lymph nodes. Both during helminth infection and in our acute HDM-driven AAI model, the absence of Notch signaling in T cells hampered Tfh formation and IgE induction. During chronic AAI, however, MedLN Tfh formation appeared unaffected even though serum IgE was strongly reduced. This finding may point to an important role for iBALT in IgE induction, paralleling the importance of iBALT for the generation of circulating protective antiviral antibodies upon influenza infection in mice (58).
Altogether, we show that in AAI Notch signaling is required to license the Th2 response via promoting lymph node egress of effector Th2 cells. The current study provides a mechanistic explanation for the previous finding that pharmacological Notch inhibition specifically during the challenge phase reduces AAI and bronchial hyperreactivity in mice (18, 20). Together with our recent observation that circulating T cells from asthma patients exhibit increased Notch expression (21), this further emphasizes that blocking of the Notch signaling pathway may represent an attractive therapeutic strategy to suppress Th2 cell-mediated inflammation in patients with allergic asthma. Given that Notch may act as an unbiased amplifier of T cell responses irrespective of T helper cell polarization (22), it is conceivable that Notch signaling not only controls lymph node egress of Th2 cells, but also of other T helper subsets in different inflammatory contexts such as respiratory infections or tumor immunosurveillance.
Methods

Mice

Wildtype (WT) mice were purchased from Envigo (Indianapolis, USA). \textit{Notch1}^{fl/fl} mice (14), \textit{Notch2}^{fl/fl} mice (24) and \textit{RBPJκ}^{fl/fl} mice (59) were crossed with CD4-cre transgenic mice (25), with CD2-Gata3 Tg mice (32), with OTII mice (60) or with Gata3-YFP reporter (GATIR) mice (38, 61). Dll4/Dll4\textsubscript{AcCd19/ΔCd19} mice have previously been described (28). All mice were bred on a C57BL/6 background in the Erasmus MC animal facility under specific-pathogen free conditions and genotyped by PCR as described (14, 24, 25, 32, 59). Both male and female 6-14-week-old mice were used in experiments. Mice were given ad libitum access to food and water.

Preparation of single cell suspensions

Directly after harvest, spleen, lymph nodes, thymus and lungs were mechanically disrupted in a 100 μm cell strainer (BD Falcon, Bedford, MA, USA). To prepare single-cell suspensions from bone marrow (BM), femurs and tibias from mice were cleaned with 70% ethanol and mechanically disrupted in RPMI 1640 containing GlutaMAX-I, after which cells were separated from bones using a cell strainer. Erythrocytes in BM and lung homogenates were lysed for 1 min using osmotic lysis buffer.

\textit{In vivo} mouse studies

**HDM-driven AAI.** Acute HDM-mediated AAI was induced by first sensitizing mice with 1 or 10 μg (as indicated in the figures) HDM (Greer, Lenoir, NC, USA; (endotoxin: 1397.5 EU/vial; protein: 5.59 mg/vial) intranasally (i.n.) dissolved in 40 μl PBS (Invitrogen, Carlsbad, CA, USA) or with PBS alone. At day 7-10, mice were i.n. exposed to 10 μg HDM (in 40 μl PBS) for 5 consecutive days. During HDM/PBS treatments, mice were anesthetized with isoflurane. Mice were sacrificed and analyzed 4 days after the last challenge. Broncho-alveolar lavage fluid (BAL) was obtained by flushing the lungs three times with 1 mL PBS containing 0.5 mM EDTA (Sigma-Aldrich, Darmstadt, Germany). Chronic HDM-mediated AAI
was induced and lung function was measured following increasing doses of nebulized methacholine (0.4–25 mg/mL) using a restrained whole-body plethysmograph (EMKA) under urethane sedation.

**In vivo OVA-specific T cell responses.** In brief, CD4+ T cells were isolated from spleen and lymph nodes of OTII mice using a CD4+ T cell MACS isolation kit (Miltenyi Biotec, Bergisch Gladbach, Germany) and were stained with 0.5 mM carboxyfluorescein succinimidyl ester (CFSE; Thermo Fisher Scientific, Waltham, MA, USA) for 10 minutes at 37°C. A total of 2·10^6 OTII cells were transferred intravenously into WT recipients. The next day, mice were exposed intranasally to 5 or 20 μg OVA (Endotoxin-free, Hyglos, Bernried am Starnberger See, Germany) and 50 μg HDM. Animals were sacrificed 72 hours later for FACS analyses.

**In vivo transfer of polarized OTII Th2 cells.** To study the role of Notch in the maintenance of Th2 responses, 10·10^6 in vitro polarized Th2 OTII cells were injected in WT recipients. For Th2 polarization, naïve T cells were isolated from spleen and lymph nodes of OTII mice using a CD4+ T cell MACS isolation kit and were subsequently sorted using a FACS Aria equipped with BD FACS Diva software (BD Biosciences, San Jose, CA, USA). Cells were selected on negativity for DAPI (Invitrogen). Doublets were depleted using side scatter- and forward scatter width and height and cells were further gated as CD4+CD62L+. A list of all used fluorochrome labeled antibodies can be found in Supplemental Table 1. CD4+CD62L−CD44+ naïve T cells were cultured in 96-well flat-bottom plates pre-coated with 10 μg/ml anti-CD3 (BD Biosciences, 145-2C11) and 10 μg/ml anti-CD28 (BD Biosciences, 37.51) in PBS (65 μl per well) in T cell medium (IMDM medium containing 10% FCS, 5x10^{-5} M β-mercaptoethanol, 1X glutamax and 55 μg/ml gentamicin; Lonza) for 7 days in the presence of IL-4 (10 ng/mL, PeproTech), anti-IFN-γ (5 μg/mL; BD Biosciences B27) and anti-IL-12/23 p40 (5 μg/mL; BD Biosciences C17.8). After transfer of polarized Th2 cells, mice were challenged intratracheally for 4 consecutive days with 50 μg OVA and 10 μg HDM. Mice were analyzed 1 day after the last challenge. We did not administer OVA into the lung prior to Th2 cell transfer to preclude direct migration of these cells into allergen-primed lungs, thereby bypassing the MedLN.
Adoptive transfer of T cell fractions from MedLN. To evaluate the lung homing capacity of Notch-deficient MedLN OTII Th2 cells, we transferred in vitro polarized WT or Notch-deficient OTII Th2 cells into WT mice followed by i.n. challenges with OVA and HDM as described above. One day after the last OVA-HDM treatment, mice were sacrificed and total CD4+ T cells were purified from five pooled MedLNs using a CD4+ T cell MACS isolation kit (Miltenyi Biotec), followed by labeling with CellTrace Far Red (Thermo Fisher Scientific, Waltham, MA, USA) according to the manufacturer’s instructions. Subsequently, 2-4·10^6 total CD4+ T cells – of which ~10-30% were OTII cells – were adoptively transferred into secondary WT recipient mice, which were sensitized intratracheally with 50 µg OVA and 10 µg HDM one day before transfer. Secondary recipients were sacrificed three hours after transfer for analysis by flow cytometry.

Analysis of Notch ligand induction in MedLNs. To investigate the induction of Notch ligands on stromal cells and DCs in the MedLN by HDM, WT mice were treated i.n. with 50 µg HDM dissolved in 40 µl PBS or with PBS alone and sacrificed after 72 hrs.

DC-OTII cell co-cultures
GM-CSF bmDCs were generated as described(55, 62) and stimulated overnight with 5 µg/ml HDM or 100 ng/ml LPS (Enzo life sciences, Farmingdale, NY, USA) in combination with variable concentrations of endotoxin-free OVA as indicated in the figure legends. Naïve T cells were isolated from spleen and lymph nodes of OTII mice using a CD4+ T cell MACS isolation kit and were subsequently sorted using a FACS Aria equipped with BD FACS Diva software (BD Biosciences, San Jose, CA, USA), as described above. GM-CSF bmDCs (5·10^3) were cultured with 1·10^5 CFSE labeled naïve T cells for four days at 37°C, after which cells were analyzed using flow cytometry.

T helper cell cultures
Naïve T cells were obtained as described above and polarized to Th2 conditions as described above. For Th1 polarization, naïve T cells were cultured on anti-CD3/CD28 coated plates in T cell medium (see
above) with 10 ng/ml IL-12 (R&D) and 5 mg/ml anti-IL-4 (kindly provided by Louis Boon, Bioceros, Utrecht). For Th17 polarization, naïve T cells were cultured on anti-CD3/CD28 coated plates in T cell medium with anti-IL-4 (5 µg/ml), anti-IFN-γ (5 µg/mL), TGF-β (3 ng/ml; R&D) and IL-6 (20 ng/ml; R&D).

**Flow cytometry**

Single cell suspensions were stained with a mixture of fluorochrome labeled antibodies in FACS buffer containing 0.25% BSA, 0.5 mM EDTA, 0.05% NaN₃ in PBS (55, 57). A list of all fluorochrome labeled antibodies that were used can be found in **Supplemental Table 1**. Data was acquired using an LSR II flow cytometer and FACS Dive software 6.1 (BD Biosciences) and analyzed using Flowjo 9.8.5 (tree Star Inc., Ashland, OR, USA).

To measure phosphorylation of S6 ribosomal protein by flow cytometry, total spleen cells were stained for extracellular markers and stimulated for 3 hours with combinations of anti-CD3 and anti-CD28 (both BD biosciences). Cells were then fixed with Cytofix and permeabilized with Phosflow perm buffer III (BD Biosciences) and stained for anti-pS6 ribosomal protein (S240/244; Cell Signaling Technology).

**Histology**

Five-µm-thick paraaffin-embedded lung sections were obtained and stained using haematoxylin/eosin (HE), periodic acid-Schiff (PAS) or Masson-trichrome (Sigma-Aldrich). For immunohistochemistry, Lungs were inflated with OCT, snap frozen in liquid nitrogen, and stored at −80°C; frozen sections were fixed in acetone, endogenic peroxidase was blocked and immunohistochemical double staining was performed using standard procedures. Antibodies are listed in **Supplemental Table 1**.
Cytokine and immunoglobulin measurements

Cytokines were quantified by commercial enzyme-linked immunosorbent assay (ELISA) for IL-5 (eBioscience), IL-13 (R&D, Minneapolis, MN, USA), IgE (BD biosciences) and IgG1 (BD biosciences) according to the manufacturers’ protocol. HDM-specific IgE and IgG1 (antibodies from BD biosciences) were measured as follows. A NUNC MaxiSorp flat-bottom 96-well plate (Sigma, St Louis, MO) was coated with 2 µg/ml anti-mouse IgE (for HDM-specific IgE, BD Pharmingen) or 10 µg/ml HDM (for HDM-specific IgG1) in PBS overnight at 4°C. Next day the plates were washed three times with wash buffer (PBS containing 0.05% Tween-20) and blocked for 1 hour with either PBS containing 1% BSA (for HDM-specific IgE) or ELISA buffer (50 mM Tris(hydroxymethyl)aminomethane, 136.9 mM NaCl, 2 mM Ethylene-diamine-tetraacetic acid, 0.5% BSA and 0.05% Tween, dissolved in 1000 ml H2O, pH 7.2). Serum samples were incubated at room temperature for 2h and washed three times. For HDM-specific IgE, samples were labeled with biotin-conjugated HDM and incubated for 2 hours, washed three times and incubated with horseradish-peroxidase for 1h. For HDM-specific IgG1, samples were labeled for 1h with 0.5 µg/ml biotinylated-IgG1 followed by incubation with horseradish-peroxidase for 30 min. After labeling, plates were washed three times and incubated with 0.4 mg/ml o-Phenylenediamine dihydrochloride (OPD; Sigma) for 20 min. Reactions were stopped through addition of 4M H2SO4 and plates were read at 490 nm.

RNA extraction and quantitative real-time PCR

RNA was extracted using RNeasy Micro Kit (Qiagen) according to manufactures’ protocol. RNA was synthesized into cDNA using RevertAid H Minus Reverse Transcriptase and random hexamer primers in the presence of RiboLock RNase inhibitor (Thermo Fisher Scientific). For qRT-PCR reactions, probes from the Universal ProbeLibrary Set (Roche Applied Science) and Taqman Universal Mastermix were used (Applied Biosystems, Foster City, CA, USA). qRT-PCR reactions were performed using an Applied Biosystems Prism 7300 Sequence Detection System (Applied Biosystems). Primers were designed using transcript sequences obtained from https://www.ensembl.org/ and were specific for Dtx1 (forward:
5’-CGCCTGATGAGGACTGTACC3’, reverse: 5’-CCCTCATAGCCAGATGCTGTG-3’, probe #28), Cx3cr1 (forward: 5’-AAGTTCCCTTCCCATCTGCT-3’, reverse: 5’-CAAAATTCTCTAGATCCAGTTCAAGG-3’, probe 10), Sell (forward: 5’-GGAGCATCTGGAAAATGGTC-3’, reverse: 5’-TTGATCTTTGAGAAACTTCTGTGGG-3’, probe 21), Jag1 (forward: 5’-ACCAGACGGCAACAAACACT-3’, reverse: 5’-GACCCATGCGTGGACTG-3’, probe 97), Jag2 (forward: 5’-CGTCATTCCCTTCTGCTGTTG-3’, reverse: 5’-CCTCATCTGGATGCAGTGCA-3’, probe 95), Dll1 (forward: 5’-GGGCTTCTCTGCTCAAC3’, reverse: 5’-TAAGAGTTGCCGAGGTCCCCAC3’, probe 103) and Dll4 (forward: 5’-GAGGAACGAGTGTGTGGATTG-3’, reverse: 5’-GTCCCCATACAGGATGCAATGTG-3’, probe 3). Expression levels were normalized to glyceraldehyde-3-phosphate dehydrogenase (Gapdh) levels (forward: 5’-TTCACCACCATGGAGAAGGC-3’, reverse: 5’-GGCATGGACTGCTGTTCAAGG-3’, probe TGCATCCTGCACCAACTG). Primers were checked for specificity and efficacy using standard criteria.

**RNA-sequencing (RNA-Seq)**

RNA was extracted from the following populations: 1) WT (N1N2+/+) and Notch-deficient (N1N2ACD4/ACD4) OTII Th2 cells directly after in vitro polarization (n=2 biological replicates per genotype) and 5 days after in vivo transfer and OVA/HDM-treatment from MedLNs (n=3 WT and n=4 Notch-deficient biological replicates); 2) WT (N1N2-/-) Gata3+ Th2 (YFP+) cells isolated from BAL fluid or MedLNs of GATIR mice on an acute HDM-driven AAI protocol (n=3 biological replicates per tissue). Biological replicate RNA samples were prepared from pooled cell populations collected from 3-5 mice per genotype. RNA samples were then used to prepare RNA-Seq libraries with Smart-seq2 methodology and sequenced on an Illumina HiSeq2500 (single read mode, 51 bp read length) according to the Illumina TruSeq Rapid v2 protocol.
Computational analysis of RNA-Seq data

HISAT2 was used to align reads to the mouse genome (mm10 build) (63). Scaling of samples as well as statistical analysis was executed using the R package DESeq2 (64) as implemented in HOMER (getDiffExpression.pl -DESeq2) (65); genes with >0.5 absolute log2 fold change and adjusted \( P < 0.05 \) (Wald test, corrected for multiple testing) were considered differentially expressed (Supplemental Table 2). Reads Per Kilobase Million (RPKM) values per gene were generated using HOMER (analyzeRepeats.pl rna mm10 -count exons -condenseGenes -norm 1e7 -rpkm). Principal component analyses, hierarchical clustering (Ward’s method) and the generation of volcano plots and Venn diagrams was conducted using standard R scripts (i.e. prcomp(), hclust(), ggplot(); executed from R Studio v1.1.383). Pathway enrichments were calculated with Metascape (http://metascape.org/) or GSEA (http://software.broadinstitute.org/gsea/index.jsp, using a pre-ranked list of differentially expressed genes ordered by fold changes).

Statistics

For statistical analysis of all data except for the analysis of RNA-Seq experiments (see above), a non-parametric Mann-Whitney U-test or Kruskal-Wallis test with correction for multiple testing (FDR method) was performed using GraphPad Prism software (version 5.01, La Jolla, USA). \( P \) values below 0.05 were considered significant.

Data availability

RNA-Seq data was deposited in the Gene Expression Omnibus (GEO) under accession number GSE125358.

Approval of animal experiments

All experiments involving animals were approved by the Erasmus MC Animal Ethics Committee.
Author contributions

I.T. designed and performed experiments, analyzed the data and wrote the manuscript. A.K. and A.v.S. designed, performed and analyzed experiments; M.d.B., M.L., M.v.N., A.v.d.B., I.B. and O.B.J.C. performed experiments; W.v.IJ. supervised RNA-sequencing efforts; R.S. designed experiments, analyzed the data and wrote the manuscript. R.W.H. designed experiments, wrote the manuscript and supervised the study.

Acknowledgements

The authors like to thank J. Rip, W.M.E. Hendrikx, F. Cornelissen, members of the Biomics core and Animal Facilities (Erasmus MC Rotterdam) as well as L. Hesse (UMCG, Groningen) for their technical assistance. We also acknowledge T. Cupedo (Erasmus MC) and D. Amsen (Sanquin, Amsterdam) for helpful discussions, as well as H.J. Fehling (Ulm, Germany) and F. Radtke (Lausanne, Switzerland) for kindly providing the Gata3-YFP reporter (‘GATIR’) mice and Dll4ACcl9/ΔCcl19 mice, respectively. This study was partly supported by Lung Foundation Netherlands Grants 3.2.12.087 and 3.2.12.067. R.S. is supported by an NWO Veni Fellowship (Grant No. 91617114) and an Erasmus MC Fellowship.

cells from MedLNs and lungs of mice treated with HDM and OVA. (D) PCA using expression values of the 681 DE genes (Figure 6C) from MedLN WT and Notch-deficient OTII Th2 cells as well as Gata3+ MedLN and bronchoalveolar lavage (BAL) Th2 cells from GATIR mice treated with HDM (as in Figure 1A). The 1D side-plot illustrates how PC2 clusters WT with OTII MedLN cells and WT BAL Th2 cells with N1N2ΔCD4ΔCD4 OTII MedLN Th2 cells. (E) Expression fold changes for indicated genes in Gata3+ Th2 cells from MedLN versus BAL or WT versus Notch-deficient OT-II Tg MedLN Th2 cells (representative of three experiments, color code as in panel D). (F) RBPJκ ChIP-Seq signal (from the 8946 T-ALL cell line (51)) in the Dtx1 and Gata3 (both canonical Notch target genes) and the S1pr1 and Klf2 loci. (G) Quantitative PCR measurements of Notch ligand genes in populations of CD11b+ migratory dendritic cells (DCs), lymphoid endothelial cells (LECs) and fibroblastic reticular cells (FRCs) from the MedLN of mice 3 days after PBS or HDM exposure.
Figure 8. MedLN-derived N1N2ΔCD4ΔCD4 Th2 cells have the capacity to migrate into the lungs after adoptive transfer. (A) Sequential adoptive transfer protocol: in vitro polarized OTII T cells (either WT or N1N2ΔCD4ΔCD4) were transferred intravenously (i.v.) into primary WT recipient mice, which were subsequently challenged with OVA/HDM for 4 days. Total CD4+ T cell fractions from the MedLNs of these mice were APC-labelled and adoptively transferred into secondary WT recipient mice that were treated intranasally with OVA one day before transfer and analyzed after 3 hours. (B) Flow cytometric analysis of splenic cells from secondary recipient mice that received MedLN CD4+ T cells from the indicated mouse genotypes, showing the gating of CD3+CD4+APC+ labeled cells (left) and the TCRβ5+TCRα2+ OTII Th2 cells from this population (right). (C) Analysis of TCRβ5+TCRα2+ labeled Th2 cells in the lungs (left) or MedLN (right) of secondary recipient mice. (D) Quantified homing capacities of wildtype and Notch1/2-deficient OTII T cells after 2 consecutive transfers. Data are shown as a ratio of the percentage TCRβ5+TCRα2+APC+ OTII cells of the total CD3+CD4+ T cells in MedLN, lung and blood over the equivalent percentage of OTII cells in the spleen. Depicted are individual values.
from 2-3 biological replicates, together with the mean ± SEM. (E) Model summarizing the role of Notch signaling in controlling Th2 cell trafficking in AAI via activation of the KLF2-S1PR1 axis. In lymph node CD4+ Th2 cells, Notch receptor-ligand interactions induce nuclear translocation of the Notch intracellular domain (NID) that, together with its coactivator MAML and the DNA-binding protein RBPJκ, serves as a transcriptional activator. In Th2 cells that are ready to migrate to the lungs this Notch complex activates the KLF2-S1PR1 axis to promote lymph node egress. This allows Th2 cells to migrate to the lung and establish eosinophilic allergic airway inflammation (AAI).
