Abstract

Brown adipose tissue (BAT), as the main site of adaptive thermogenesis, exerts beneficial metabolic effects on obesity and insulin resistance. BAT has been previously assumed to contain a homogeneous population of brown adipocytes. Utilizing multiple mouse models capable of genetically labeling different cellular populations, as well as single-cell RNA sequencing, and 3D tissue profiling, we discovered a new brown adipocyte subpopulation with low thermogenic activity co-existing with the classical high thermogenic brown adipocytes within the BAT. These low thermogenic brown adipocytes had significantly lower \textit{Ucp1} and \textit{Adipoq} expression, larger lipid droplets, and lower mitochondrial content. Functional analyses showed that the low thermogenic brown adipocytes have significant lower basal mitochondrial respiration, and they are specialized in fatty acid uptake. Upon changes in environmental temperature, the two brown adipocyte subpopulations underwent dynamic inter-conversions. Cold exposure converted low thermogenic brown adipocytes into high thermogenic cells, and a thermoneutral environment had the opposite effect. This recruitment of high thermogenic brown adipocytes by cold stimulation is not affected by high fat diet feeding, but significantly declined with age. Our results revealed a high degree of functional heterogeneity of brown adipocytes.
Introduction

Brown adipose tissue (BAT) is a thermogenic organ that is thought to play an important role in human energy homeostasis (1-3). Upon activation, brown adipocytes within the BAT can function as an effective energy sink, burning and disposing excess lipids and glucose (4-6). In recent years, progress has been made in rodents and humans in understanding the function and physiological impact of BAT. It is now well accepted that recruiting and activating BAT can correct dyslipidemia and prevent obesity-related metabolic disorders (7-10). Although functional heterogeneity has recently been reported in white and beige adipocytes within an individual fat depot (11-14), BAT is still viewed to have a highly homogeneous population of brown adipocytes. Interestingly, some previous studies have indicated that thermogenesis is not uniformly activated in all brown adipocytes. For instance, brown adipocytes have been shown to have a heterogeneous expression of Uncoupling Protein 1 (UCP1) (15, 16). Moreover, in vitro cultured brown adipocytes showed heterogeneous mitochondrial membrane potential (17, 18). However, the thermogenic and metabolic heterogeneity of brown adipocytes within the same BAT in vivo remains largely uncharacterized.

Results

To better understand brown adipocyte dynamics in vivo, we used the AdipoChaser-LacZ mouse model we previously developed to label brown adipocytes. This model is a doxycycline (dox)-based, tet-responsive labeling system for the inducible, permanent labeling of Adiponectin (Adipoq) expressing cells as LacZ+ cells (Supplemental Figure 1A) (19, 20). To our surprise, at room temperature (24°C), despite the uniform labeling of white adipocytes (19, 20), only 38% of total brown adipocytes in the BAT were labeled as LacZ+ (blue) cells, and these cells distribute in
a patchy pattern (Figure 1, A and B). The percentage of LacZ+ brown adipocytes is significantly higher (76%) when mice were housed in a cold environment (6°C), and significantly lower (6%) when mice were housed in a thermoneutral environment (30°C) (Figure 1, A and B). However, Adipoq mRNA in the whole BAT was slightly increased when mice were at 6°C, and was not altered when mice were in 30°C (Supplemental Figure 1B). When we treated AdipoChaser-LacZ mice with β3-adrenergic receptor agonist to stimulate thermogenesis (Figure 1C), we observed a similar percentage of LacZ+ brown adipocytes as upon cold exposure (67%) (Figure 1, D and E).

Is the increase of LacZ+ brown adipocytes during cold exposure due to de novo adipogenesis? And likewise, is the decrease of LacZ+ brown adipocytes during thermoneutral exposure due to cell death? When we pre-labeled mice at 24 °C and pulse-chased at 6°C or 30°C, the percentages of LacZ+ brown adipocytes (40%) remained the same as when they were at 24°C (Figure 1, F and G). When we pre-labeled mice at 30°C and pulse-chased at 6°C, the percentages of LacZ+ brown adipocytes (5%) remained the same as when they were at 30°C (Figure 1H). Likewise, when we pre-labeled mice at 6°C and pulse-chased at 30°C, the percentages of LacZ+ brown adipocytes (73%) remained the same as when they were at 6°C (Figure 1I). Meanwhile, body weight, BAT weight, and brown adipocyte cell size were not altered when mice were in a cold environment (Supplemental Figure 1, C–E). Moreover, we have not observed significant apoptosis of brown adipocyte by active Caspase 3 staining (Supplemental Figure 2, A–D). Therefore, there are dynamic inter-conversions between these two brown adipocyte subpopulations upon temperature change, and we have no evidence of significant adipogenesis or cell death.

We subsequently looked into the subcellular structure of these two brown adipocyte
subpopulations through electron microscopy imaging. X-gal, when cleaved by β-galactosidase, produces 5,5'-dibromo-4,4'-dichloro-indigo-2, an intense blue product which is insoluble. Under the electron microscope, this blue product can be observed as crystals (21, 22), and the LacZ+ brown adipocytes can be distinguished by this feature. Compared to the LacZ+ brown adipocytes (adiponectin high-expressing), the LacZ- brown adipocytes had significantly lower mitochondrial number/content and much larger lipid droplets (Figure 2, A–D). We then switched to an AdipoChaser-mT/mG system we reported recently (20, 23) (Supplemental Figure 3A), and confirmed that Adipoq is selectively expressed in a subpopulation of brown adipocytes in a patchy pattern (Supplemental Figure 3, B and C). In the isolated primary brown adipocytes, the GFP- (Adipoq low-expressing) brown adipocytes had significantly higher mitochondrial membrane potential (Supplemental Figure 3, D–F), indicating that these cells have lower mitochondrial membrane depolarization and uncoupling rate (24). We also generated the AdipoChaser-YFP mice (Supplemental Figure 3G), as YFP is relative easier for immunofluorescence staining. When we labeled mice in 6°C, the Adipoq high-expressing (YFP+) brown adipocytes largely overlapped with UCP1 high expressing cells (Figure 2E). Thus, Adipoq expression positively correlates with UCP1 protein expression. Overall, these results suggest that the Adipoq low-expressing brown adipocytes are morphologically and molecularly different from the Adipoq high-expressing brown adipocytes. When we pre-labeled mice at 24°C and pulse-chased at 6°C, there were significantly more UCP1+ cells than YFP+ cells, and most of the pre-labeled YFP+ brown adipocytes co-labeled as UCP+ cells (Figure 2F). This result confirms that the YFP- brown adipocytes labeled at 24°C could convert into UCP1 high expressing cells at 6 °C.
We next set out to verify the brown adipocyte heterogeneity through single-cell RNA-sequencing (scRNA-seq) of primary brown adipocytes isolated from the BAT of adult mice housed at 24°C. Two major brown adipocyte subpopulations were clustered: brown adipocytes with high thermogenic activity (BA-H, 2,352 cells, including three sub-clusters, BA-H1, BA-H2, and BA-H3) and brown adipocytes with low thermogenic activity (BA-L, 1,250 cells) (Figure 3A). These two populations differed by the expression level of Ucp1, as well as Adipoq (Figure 3, B and C). Two other clusters of cells were identified as white adipocytes (WA, 197 cells) and non-adipocytes (NA, 34 cells) (Figure 3A). This white adipocyte cluster served as a nice internal control in the subsequent analysis. In the BA-L subpopulation, expressions of genes related to thermogenesis, such as Cidea, Elovl6, and oxidative phosphorylation (OXPHOS) complexes were extremely low, close or lower than the white adipocytes in the WA cluster (Figure 3D, Supplemental Figure 4 and Supplemental Figure 5, A–E). Similarly, the BA-L subpopulation had very low expression levels of genes related to lipolysis, glycolysis, fatty acid oxidation, and the TCA cycle (Figure 3E and Supplemental Figure 6, A–C). Moreover, two newly identified pathways that have been described and may be essential for the positive regulation of thermogenesis, ROS (25) and succinate metabolism (26), were also only enriched in the BA-H subpopulation (Supplemental Figure 6, D and E). Therefore, brown adipocytes within the BA-L subpopulation belong to a novel and unique type of brown adipocyte with low thermogenic activity.

Notably, the BA-L subpopulation had significant high expression levels of genes related to fatty acid uptake (Figure 2F and Supplemental Figure 7A). This subpopulation was also enriched for genes that are essential for cell-to-cell trafficking (27) (Supplemental Figure 7B), as well as UCP1-independent thermogenesis through the futile cycle of creatine metabolism (28) and tight junction
(Supplemental Figure 7, C and D). Thus, brown adipocytes within the BA-L subpopulation hold a unique metabolic status, and the function of these cells is potentially fundamentally different from the cells within the BA-H subpopulation.

What regulates the functional heterogeneity between the two brown adipocyte subpopulations? Interestingly, PPARγ (29) and C/EBPα (30), the two master transcription factors that regulate adipocyte function (31, 32), have distinct expression patterns in these two subpopulations. Surprisingly, Pparg was relatively enriched in the BA-L subpopulation (Supplemental Figure 7E), consistent with the expression patterns of its downstream targets Cd36 and Fabp4 (Figure 2F). In contrast, Cebpa was enriched in the BA-H subpopulation (Supplemental Figure 7E). These data indicate that these two factors may act as upstream regulators responsible for the distinct transcriptional profiles of the two brown adipocyte subpopulations. As expected, the expression of white adipocyte marker resistin (Retn) (Supplemental Figure 7F) was only detected in the WA cluster. Among the three BA-H sub-clusters, thermogenic genes had the highest expression levels in BA-H3 (Supplemental Figure 4). The sub-clusters BA-H1 and BA-H2 were enriched for genes that related to mitochondrial biogenesis and insulin responsiveness (33-35) (Supplemental Figure 7H).

We next performed immunofluorescence co-staining to confirm the protein levels of these genes identified through scRNA-seq. In the AdipoChaser-YFP mice (Figure 4A), YFP+ cells (Adipoq high expressing brown adipocytes) primarily overlapped with Elovl6 (Figure 4B), as well as SDHA and COX IV (Figure 4, C and D); while large numbers of YFP+ brown adipocytes did not
overlap with FABP4 (Figure 4E), as well as PPARγ (Figure 4F). Thus, the protein levels of these important genes match with the expression pattern demonstrated by the scRNA-seq results.

To test whether the two brown adipocyte subpopulations have different mitochondrial respiratory capacity, we separately collected the two freshly isolated brown adipocyte subpopulations from BAT through mild centrifugation. With the Ucp1-GFP mice, a tet-responsive labeling system under the control of the Ucp1 promoter (Figure 5A), isolation and separation were verified based on the GFP signal intensity (Figure 5B). We first measured mitochondrial function through a Mito Stress Test Kit (Figure 5C). The BA-H, BA-L, white adipocyte, and primary BAT stromal vascular fraction (SVF) showed distinct levels of oxygen consumption as judged by the oxygen consumption rate (OCR). As the ATP synthesis rate is relatively low in brown adipocytes due to uncoupled respiration, it is not surprising that oligomycin (ATP synthase inhibitor) did not significantly alter OCR in brown adipocytes; while oligomycin decreased OCR by 59% in SVF, and by 20% in white adipocyte (Figure 5C). The basal respiration in the BA-H population was around two-fold higher compared to the BA-L population. Both brown adipocyte subpopulations had significantly higher basal respiration compared to white adipocyte and the SVF (Figure 5D). Interestingly, the BA-H population had a maximal respiration rate very close to the BA-L population, indicating these brown adipocytes have high mitochondrial potential and are readily recruitable (Figure 5E). The BA-H population isolated through mild centrifugation contains a low percentage of SVF. To obtain a purer BA-H population, we isolated the BA-H population from AdipoChaser-mT/mG mice through a magnetic bead-based method taking advantage of the membrane-bound GFP. The OCR levels of both BA-L and BA-H subpopulations obtained through this alternative method were much lower compared to the cells obtained through mild
centrifugation, which may due to the much longer processing time involved for the isolation (Figure 5F). However, the difference in basal OCR is consistent between the two methods (Figure 5C and Figure 5F). Moreover, both BA-L and BA-H populations showed responses to norepinephrine, but the BA-H population had a more robust increase in the OCR (Figure 5F). We also measured the fatty acid uptake rate in the two brown adipocyte subpopulations, and consistent with the high Fabp4 mRNA and protein level (Figure 3F and Figure 4D), the BA-L population displayed significantly higher rates of fatty acid uptake (Figure 5G). This result is consistent with a recent report, which demonstrated that the uptake of nutrients by adjacent murine brown adipocytes is variable (36). Overall, these results demonstrate that the two brown adipocyte subpopulations have fundamentally distinct function and metabolic profiles.

We performed 3D profiling of BAT from the Ucp1-GFP mice housed at 24 °C. UCP1+ (GFP+) brown adipocytes distributed in a patchy pattern (Figure 5H and Supplemental Video 1), confirming the scRNA-seq result that Ucp1 is also distinctly expressed in different subpopulations of brown adipocytes. The thermogenesis of brown adipocytes is governed by sympathetic innervation (37). The 3D architecture showed that compared to the less innervated white adipose tissues (38, 39), almost every brown adipocyte is heavily innervated with sympathetic neurons (Figure 5H and Supplemental Video 1). Thus, the diversity in thermogenic activity observed in these two brown adipocyte subpopulations is not determined by sympathetic innervation. Notably, the expression level of β3-adrenergic receptor Adrb3 was enriched in the BA-H subpopulation (Supplemental Figure 7G). Therefore, the diverse thermogenic activity may be determined by the difference in the responsiveness of brown adipocyte to β3-adrenergic signals.
Does BAT emerge developmentally as two distinct subpopulations? We looked into the $\textit{Adipoq}$ expression in brown adipocytes during development, by exposing AdipoChaser-LacZ mice to dox diet at various embryonic and postnatal stages (Figure 6A). When we exposed mice to dox diet during E3–10, very few (less than 1%) of brown adipocytes were labeled as LacZ+ cells upon examining the tissue at 4 weeks of age (Figure 6B). When mice were exposed to dox diet during E7–E14, brown adipocytes showed a heterogeneous pattern of LacZ+ cells, with some regions carrying more than 92%, and other regions displaying less than 10% LacZ+ signal when examined at 4 weeks of age (Figure 6C). When mice were exposed to dox diet during E9–E16, brown adipocytes showed uniform positive labeling of LacZ+ cells when examined at 4 weeks of age (Figure 6D). These observations indicate that brown adipocytes differentiation is initiated as early as E10, and all brown adipocytes have initiated differentiation and started to express $\textit{Adipoq}$ by E16. Thus, adiponectin can be used as a terminal differentiation marker for both brown adipocytes as well as for white adipocytes (19). At the age of 27 weeks, for the mice that were exposed to dox diet during E18–P4, the brown adipocytes continued to display a uniformly positive LacZ labeling (Figure 6E), indicating that the turnover rate for brown adipocytes is extremely low in the adult stage at room temperature. Thus, the $\textit{Adipoq}$ low-expressing brown adipocytes are not newly generated postnatally.

We subsequently narrowed down the time frame during which the BAT develops heterogeneity through the inter-conversion (Figure 6F). When AdipoChaser-LacZ mice were exposed to dox diet during E7–P2, their brown adipocytes showed a uniform LacZ+ labeling when examined at 8 weeks of age (adult stage) (Figure 6G). When mice were exposed to dox diet during P3–P10 or P7–P14, 56% or 42% of their brown adipocytes were labeled as LacZ+ cells, which is close to the
percentage at the adult stage (38% in Figure 1B). These experiments indicate that the BAT transcriptional program becomes heterogeneous shortly after birth, and the ratio of Adipoq high-expressing and low-expressing brown adipocytes becomes stable around P7.

It has been suggested that decreased BAT thermogenesis is associated with the accumulation of body fat, as well as age (40-42). Therefore, we checked if high fat diet (HFD) induced obesity reduces the inter-conversion of Adipoq low expressers to high expressers during cold exposure (Supplemental Figure 8, A and B). When AdipoChaser-LacZ mice were housed at 6°C, the percentages of LacZ+ brown adipocytes from HFD fed mice (47%) were comparable to brown adipocytes from chow-fed mice (45%) (Supplemental Figure 8, C and D). At 24°C, HFD fed mice even had higher percentages of LacZ+ brown adipocytes (23% Vs. 12%). Thus, HFD feeding does not impair the recruitment of Adipoq high-expressing brown adipocytes during cold exposure. However, even in the chow-fed group, these 21-week-old mice had a significantly lower percentage of LacZ+ brown adipocytes at both 6°C and 24°C compared to 8-week-old mice (Figure 1, A and B), indicating that there is a decline in the number of Adipoq high expressers with age. When older mice were housed at 6°C (Figure 7A), the percentage of LacZ+ brown adipocytes further dropped to below 40% (30-week-old) and 20% (60-week-old) (Figure 7, B and C). These results indicate that the ability of BAT to recruit Adipoq high-expressing brown adipocytes during cold exposure is significantly reduced with age.

**Discussion**

We report the discovery of a low-thermogenic brown adipocyte subpopulation with unique molecular and metabolic features, co-existing with the classic brown adipocytes in vivo. The
results presented here offer critical insights towards our understanding of how brown adipose tissue thermogenesis is regulated at the cellular level. The discovery of the new low thermogenic subpopulation is of great interest since this population of cells does not have typical brown adipocyte morphology and display a unique metabolic profile. However, the exact function of this subpopulation is largely unknown. These brown adipocytes have relative large lipid droplets and low mitochondrial content and extremely low respiration rate, compared to the high thermogenic subpopulation. Are these brown adipocytes in a “resting” status and are readily recruitable to convert into high thermogenic cells? Or do they have critical metabolic functions other than thermogenesis? As the low thermogenic brown adipocytes have a much higher rate of fatty acid intake, these cells may have an indispensable role for the functional integrity of the thermogenic activity of the whole BAT. The high thermogenic subpopulation represents the extensively studied classic brown adipocyte subtype, which has the potential ability to further increase Ucp1 expression and thermogenesis upon cold stimulation. It is worth to note that most of the human studies detect BAT based on glucose uptake, as BAT exhibits high uptake of fluorine-18 fludeoxyglucose on positron emission tomography (PET). This detection method may miss the lower thermogenic brown adipocytes, which have high fatty acid uptake rate.

Adiponectin is considered a white adipocyte marker since it is more abundantly expressed in the white adipocyte. However, it is not surprising to observe a higher Adipoq expression in the high thermogenic brown adipocytes, as adiponectin positively regulates mitochondrial biogenesis and activity (43-45). Recent 3-D adipose tissue imaging reveals that cold-induced generation of beige adipocytes in the subcutaneous adipose tissue depends on the density of sympathetic innervation (38, 39). Here, we show that sympathetic innervation in BAT is much denser than that in white
adipose tissue. Thus, the thermogenic heterogeneity of brown adipocytes is not correlated to sympathetic innervation. However, it is still possible that norepinephrine is differentially secreted by each sympathetic neuron. Notably, the expression level of β3-adrenergic receptor ADRB3 was enriched in the BA-H subpopulation. Therefore, the diverse thermogenic activity may be determined by the difference in the responsiveness of brown adipocyte to β3-adrenergic signals.

Developmentally, as newborn pups require much higher thermogenic activity, it is not surprising that all brown adipocytes are born as Adipoq high expressers and potentially have high thermogenic activity. Interestingly, a subpopulation of brown adipocytes gradually converts into Adipoq low expressers after birth. The establishment of heterogeneity postnataally is likely due to the heterogeneous lineages of brown adipocyte precursors during development. However, it is also possible that the two brown adipocyte subpopulations are not born to be different, and they may undergo a “switching mechanism” even at room temperature, taking dynamic turns to function as high thermogenic cells. As the interscapular BAT is the first adipose depot to develop in the mouse, BAT may serve as the primary site for adiponectin expression and secretion in these very early stages of life. When white adipose depots development initiates later in life, these tissues then take over as the primary sites for adiponectin production. When mice in the adult stage are exposed to cold, other than a conversion of BA-L into BA-H population, BAT may also undergo de novo adipogenesis, especially when mice are exposed to the cold for a long period of time (46, 47). Importantly, the conversion of low thermogenic brown adipocytes into high thermogenic adipocytes upon cold exposure is impaired with old age, but not by high fat diet feeding. This may offer a new explanation for the age-associated decline in brown adipose tissue thermogenic activity.
Future studies will need to address the metabolic functions and lineages of the low thermogenic brown adipocyte subpopulation, as well as the molecular mechanisms that regulate the interconversion between the two subpopulations. More importantly, it will be interesting to determine why the number of thermogenic high brown adipocytes declines with age. Unmasking the complex physiology of BAT thermogenesis is essential to improve our ability to identify effective therapeutic approaches for metabolic disorders. Future strategies that promote the low thermogenic brown adipocytes to convert into a population of high thermogenic cells may greatly enhance brown adipose tissue thermogenesis, which may have potential for the treatment of obesity and diabetes.

**Methods**

Detailed methods are in the Supplemental Material.

The scRNA-seq data have been deposited in NCBI GEO with the access number GSE125269.

**Statistics.** The results are shown as means ± sd. Differences were analyzed by various methods as indicated in figure legends. All measurements were taken from individual samples.

**Study approval.** The Institutional Animal Care and Use Committees of City of Hope, Duarte, have approved all animal experiments.
Author contributions

Q.A.W., P.E.S., and A.S. designed the experiments. Q.A.W., P.E.S., and L.J. wrote the manuscript. A.S., T.N., and Q.A.W. handled all the mouse experiments and performed β-gal staining. A.S. performed the mitochondrial membrane potential test and immunofluorescence staining. A.S. prepared primary brown adipocytes and X.W. conducted and analyzed scRNA-seq experiments. A.S., Q.A.W., and W.D. performed the seahorse and fatty acid intake experiment. A.S., M.J., H.Z., and B.A. performed BAT tissue clearing and three-dimensional imaging. A.S., Z.L., and M.M. performed the transmission electron microscopy. M.S., Y.L., Y.Z., and V.G. contributed to experimental design and discussion. All authors approved the final manuscript.

Figure 6. Brown adipocyte were born as adiponectin high expressors, and the heterogeneity establishes postnatally. (A) Female mice carrying only Adn-rtTA and Rosa26-loxP-stop-loxP-LacZ were bred with AdipoChaser-LacZ male mice. When these female mice were pregnant, they were exposed to dox-containing chow diet during E3–E10, E7–E14, E9–E16, or E18-P4, and kept on regular chow diet thereafter. Offspring of these female mice were genotyped, and AdipoChaser-LacZ mice of both genders were used for LacZ staining when they were 4 weeks or 27 weeks old. (B-D) Representative X-gal staining of BAT from 4-week-old AdipoChaser-LacZ mice that were on dox diet for the indicated number of days during development. (E) Representative X-gal staining of BAT from 27-week-old AdipoChaser-LacZ mice that were on dox diet during E18-P4. Scale bar: 100 μm. (F) Female mice carrying only Adn-rtTA and Rosa26-loxP-stop-loxP-LacZ were bred with AdipoChaser-LacZ male mice. When these female mice were pregnant, they were exposed to dox-containing chow diet during E7–P2, P3–P10, or P7–P14, and kept on regular chow diet thereafter. Offspring of these female mice were genotyped, and male AdipoChaser-LacZ mice were used for LacZ staining when they were 8 weeks old. (G) Representative X-gal staining of BAT from these AdipoChaser-LacZ mice that were on dox diet for the indicated number of days during development. Scale bar: 50 μm. All images are representative of three independent experiments.
Figure 7. The recruitment of BA-H during cold exposure is declined with age. (A) AdipoChaser-LacZ male mice were kept on normal chow until 30 or 60 weeks of age. Mice were then exposed to 6°C for 7 days while treated with dox-containing chow diet. (B) Representative X-gal staining of BAT from mice of different age exposed to 6°C. Scale bar: 50 μm. (C) Quantification of the percentage of LacZ-positive brown adipocytes in the total brown adipocytes. n = 11 mice (10 weeks old); 5 mice (30 weeks old); 10 mice (60 weeks old). **P < 0.01. Statistical significance was assessed using a one-way ANOVA followed by Tukey’s multiple comparisons test. All images are representative of three independent experiments.
