Abstract

Currently, an effective targeted therapy for pancreatitis is still lacking. Hereditary pancreatitis (HP) is a heritable, autosomal-dominant disorder with recurrent acute pancreatitis (AP) progressing to chronic pancreatitis (CP) and a markedly increased risk of pancreatic cancer. In 1996, mutations in \textit{PRSS1} were linked to the development of HP. Here, we developed a mouse model by inserting a full-length human \textit{PRSS1}^{R122H} gene, the most commonly mutated gene in human HP, into mice. Expression of \textit{PRSS1}^{R122H} protein in the pancreas markedly increased stress signaling pathways and exacerbated AP. After the attack of AP, all \textit{PRSS1}^{R122H} mice had disease progression to CP, with similar histologic features as those observed in human HP. By comparing \textit{PRSS1}^{R122H} mice with \textit{PRSS1}^{WT} mice as well as enzymatically inactivated Dead-\textit{PRSS1}^{R122H} mice, we unraveled that increased trypsin activity is the mechanism for R122H mutation to sensitize mice to the development of pancreatitis. We further discovered that trypsin inhibition, in combination with anti-coagulation therapy, synergistically prevented the progression to CP in \textit{PRSS1}^{R122H} mice. These animal models help us better understand the complex nature of this disease and provide powerful tools for developing and testing novel therapeutics for human pancreatitis.
Introduction

Pancreatitis, both acute and chronic, results in significant morbidity and mortality (1-3). With ~275,000 hospitalizations/year in the US (4), acute pancreatitis (AP) is the most common gastrointestinal diagnosis and costs an estimated $2.6 billion per year due to inpatient costs alone (5). The mortality of AP is 3-6%, whereas in severe cases the rate increases to 30% (6). AP also ranks as the fifth leading cause of in-hospital deaths (6). Recurrent acute pancreatitis (RAP) can progress to chronic pancreatitis (CP) which causes pain, maldigestion, diabetes mellitus, and increased risk for developing pancreatic cancer (7, 8). Currently there are no effective preventive or therapeutic strategies for this disease, primarily due to the lack of an ideal animal model mimicking the human form of the disease and our deficient understanding of its pathogenesis (9).

More than a century ago, Chiari (10) proposed that pancreatitis was an autodigestive disease. During the past three decades, researchers have revealed that premature activation of trypsinogen occurs in the pancreas of both human pancreatitis and experimental pancreatitis (11-15). Because trypsin is capable of degrading proteins and initiating other zymogen activation cascades, premature activation of trypsinogen in pancreatic acinar cells has been considered a key initiator of this disease. This notion is strongly supported by the observation that gain-of-function trypsinogen PRSS1 R122H mutations and loss-of-function mutations of the potent pancreatic serine protease inhibitor Kazal type 1 (SPINK1) have been associated with human hereditary pancreatitis (HP) (16-21). HP is a heritable, autosomal dominant, pancreatic inflammatory disorder with >80% penetrance. Clinically, HP is characterized by RAP that has an unusually early onset (age 5-23 years) and eventually develops into CP. Of note, the cumulative risk of pancreatic cancer in patients with HP is 44% by age 70 years (7, 8).

Because the biochemical characteristics of mouse and human PRSS1 are different, an animal model expressing human PRSS1R122H shall be a prototype for studying the pathogenesis and testing therapies of pancreatitis. Unfortunately, since the discovery of the PRSS1R122H mutation in HP in 1996 (20, 22, 23), mouse models of this disease have been notoriously difficult to generate (24, 25). In this study, we aim to develop a human relevant animal model of AP and CP by expressing human PRSS1R122H, elucidate its fundamental mechanisms, and discover novel effective therapies.
Results

A BAC Transgene conferred high levels of human PRSS1<sup>R122H</sup> expression.

Based on our experience with genetically engineered mouse models and recent advancements in understanding of the biochemical characteristics of mouse and human PRSS1 pioneered by Dr. Sahin-Toth (26-28), we reasoned that both the species and expression level of the PRSS1 gene were critical for successfully modeling the disease in mice. Therefore, we decided to use a human bacterial artificial chromosome (BAC) harboring the full-length human PRSS1 gene for faithful recapitulation of its expression (Figure 1A). This BAC contains full length human PRSS1 gene promoter, exons, introns, and 3-untranslated region (UTR) to ensure native gene expression regulation. An R122H point mutation was introduced using GalK-mediated recombineering (PRSS1<sup>R122H</sup>) (Figure 1A) (29). The correct mutation targeting was verified by Sanger DNA sequencing (Figure 1B). PRSS1<sup>R122H</sup> was highly expressed in the pancreas of transgenic mice made with this construct (Figure 1C). Spontaneous pancreatitis was not observed (Supplemental Figure 1); likely other stimuli are required to initiate the development of the disease. Similarly, in humans carriers of PRSS1<sup>R122H</sup> are not born with pancreatitis. Instead, their first episode of AP attack occurs at a median age of 10 years (30). However, upon stimulation of cholecystokinin (CCK) receptors, increased and prolonged trypsin activity was observed in the pancreatic acini prepared from these transgenic mice (Figure 1D) (31). This observation supports the previously established theory that the R122H mutation would disrupt an important “fail-safe” defensive mechanism against activated trypsin (20, 32) and the expression of mutant PRSS1 may sensitize the mice to the development of pancreatitis.

Transgenic expression of human PRSS1<sup>R122H</sup> led to severe acute pancreatitis.

Cerulein, an analogue of CCK, is commonly used for inducing pancreatitis in rodents (33). Because increased and prolonged trypsin activity was observed upon CCK receptor stimulation in the PRSS1<sup>R122H</sup> mice, we predicted that more severe pancreatitis would develop in these mice. Indeed, upon stimulation with cerulein (Figure 2A), pancreata from these mice displayed severe macroscopic edema as compared with those from wild-type (WT) C57BL/6J mice (Figure 2B). The pancreatic
edema was further confirmed by increased pancreas-to-body weight ratio (Figure 2C). Elevated serum amylase, a hallmark of pancreatic acinar cell damage during pancreatitis, further suggested that more severe pancreatitis developed in the PRSS1\textsuperscript{R122H} mice (Figure 2D). Histologically, the pancreata from PRSS1\textsuperscript{R122H} mice showed increased interstitial space, an indication of edema, pancreatic acinar cell damage and massive inflammatory cells infiltration (Figure 2E), lung inflammation (Supplemental Figure 2), and histology score of pancreatitis (Figure 2F). Immunohistochemical analysis revealed that CD11b-positive leukocytes included macrophages (F4/80) and neutrophils (Gr-1) (Figure 2G, and Supplemental Figure 3). The activation of the proinflammatory NF-\kappa B signaling pathway, a master regulator of inflammation (34), was measured by detecting p65 nuclear translocation (Figure 2, H and I). The upregulation of NF-\kappa B downstream cytokine expression provides an explanation for the severe pancreatic inflammation observed in the PRSS1\textsuperscript{R122H} mice (Figure 2J). The increased severity of AP in PRSS1\textsuperscript{R122H} mice was further confirmed in L-arginine-induced pancreatitis model (Supplemental Figure 4),

**Progressive pancreatic damage and activation of cellular stress signaling in PRSS1\textsuperscript{R122H} mice.**

In humans, edematous AP usually resolves within 1 to 2 weeks; however, in patients with mutant PRSS1\textsuperscript{R122H} expression AP occurs recurrently and inevitably advances to CP. Similarly, cerulein injections caused mild AP in C57BL/6J mice, which fully recovered in a few days (Figure 3A). However, in PRSS1\textsuperscript{R122H} mice cerulein-induced AP failed to resolve (Figure 3A) and was accompanied with severe edema, progressive increase of acinar cell death and inflammatory cell infiltration (Figure 3B, and Supplemental Figure 5A). TUNEL (terminal deoxynucleotidyl transferase dUTP nick end labeling) and cleaved caspase 3 immunohistochemistry revealed massive acinar cell apoptosis (Figure 3, C and D). Next, we aimed to investigate the potential cellular signaling pathways which led to acinar cell apoptosis. The tumor suppressor p53 integrates multiple stress signals into a series of diverse anti-proliferative responses. One of the most important functions of p53 is its ability to induce cell apoptosis (35). A higher level of p53 expression was detected in the pancreata of PRSS1\textsuperscript{R122H} mice compared with C57BL/6J mice (Figure 3E). The p53 target gene, Bcl-2-associated
X protein (Bax), which mediates the p53-dependent apoptotic response (36), was also dramatically increased (Figure 3E). DNA-damage response is a key mechanism to upregulate p53 expression (37). Indeed, we observed a dramatic increase in DNA damage as assessed by phospho-Histone γ-H2AX (Ser139) and 8-hydroxy-2′-deoxyguanosine (8-OH-dG or 8-OH) levels in the PRSS1<sup>R122H</sup> mice (Figure 3F). The upregulation of phosphorylated DNA damage-associated signaling molecule CHK1 (Ser345) further indicated that DNA damage signaling pathways were activated (Figure 3E).

We previously observed that active trypsin can cause endoplasmic reticulum (ER) stress (38, 39). ER stress and the generation of reactive oxygen species (ROS) are fundamental components of unchecked unfolded protein response (UPR) (40, 41). In our initial study, ER stress signaling pathways (Bip, CHOP, XBP1s, ATF4) and enzymes involved in the production of ROS (DUOX1 and GPX4) were dysregulated in the pancreata of mutant PRSS1<sup>R122H</sup> mice (Figure 3, E and G). Whether ER stress and associated ROS production contribute to DNA damage in the context of PRSS1 mutation requires further investigation.

**Chronic pancreatitis, resembling histologic features of human HP, developed in PRSS1<sup>R122H</sup> mice.**

Our data also demonstrated that after initiation of AP, pancreatic stellate cells were activated with upregulation of alpha smooth muscle actin (α-SMA) in PRSS1<sup>R122H</sup> mice but not in C57BL/6 mice (Supplemental Figure 5, B and C). We expect that increased inflammation, extended upregulation of damage signaling, and activation of stellate cells by mutant PRSS1 may perpetuate injury to the development of chronic pancreatitis. To examine the development of CP, mice were induced with cerulein and sacrificed 70 days after AP induction (Figure 4A). Significant body weight loss in PRSS1<sup>R122H</sup> mice suggested the development of severe AP at an early time point and pancreatic function insufficiency at a later stage (Figure 4B). At 70 days, macroscopically the pancreata of WT C57BL/6J mice were normal, indicating their full recovery from AP. In contrast, all PRSS1<sup>R122H</sup> mice had smaller pancreata (Figure 4, C and D). Histologic examination showed pancreas histology was normal in C57BL/6J mice while in PRSS1<sup>R122H</sup> mice developed chronic pancreatitis (Figure 4, E and F). Acinar cell loss, fat replacement, fibrosis, and precancerous pancreatic intraepithelial neoplasia
(PanIN) lesion formation were evident in PRSS1\textsuperscript{R122H} mice (Figure 4E). These histopathologic features were similar to those observed in human HP caused by PRSS1 mutations (Figure 4E). Thus, this novel mouse model with the expression of human PRSS1\textsuperscript{R122H} mimics the features of human HP (42).

**PRSS1\textsuperscript{R122H} mice were more susceptible to cerulein-induced acute pancreatitis than PRSS1\textsuperscript{WT} mice**

Next, we aimed to discern the specific roles of the R122H mutation in determining the severity of pancreatitis and to exclude that the severe pancreatitis, which developed in the PRSS1\textsuperscript{R122H} mice, was solely caused by over-expression of PRSS1. For this purpose, we developed a transgenic mouse line with the same bacterial artificial chromosome to express WT human PRSS1 (PRSS1\textsuperscript{WT}, no R122H mutation) (Figure 5A) and compared the severity of pancreatitis between the PRSS1\textsuperscript{WT} mice and PRSS1\textsuperscript{R122H} mice. PRSS1 protein expression levels were similar in these transgenic mouse lines (Figure 5B). Initially, trypsinogen activation in response to CCK was measured in primary pancreatic acinar cells isolated from PRSS1\textsuperscript{R122H} and PRSS1\textsuperscript{WT} mice (Figure 5C). Our data indicated that pancreatic acinar cells from PRSS1\textsuperscript{R122H} mice were more sensitive to lower concentrations of CCK stimulation (Figure 5C). Next, PRSS1\textsuperscript{R122H} and PRSS1\textsuperscript{WT} mice were administrated with a single intraperitoneal (IP) injection of cerulein at various doses and pancreatitis was evaluated 24 hours after injection. We found that PRSS1\textsuperscript{R122H} mice developed more severe pancreatitis at lower doses of cerulein than PRSS1\textsuperscript{WT} mice as manifested by increased pancreatic edema (Figure 5D), elevated serum amylase levels (Figure 5E), and histologic pancreatic inflammation (Figure 5, F and G). These data confirmed that the R122H mutation of PRSS1 did sensitize transgenic mice to the development of AP more severe than PRSS1\textsuperscript{WT} mice and provides an explanation why human patients with PRSS1 R122H mutation are more prone to the development of acute pancreatitis. However, at maximum stimulation both PRSS1\textsuperscript{WT} mice and PRSS1\textsuperscript{R122H} produced the same amount of trypsin. With maximum stimulation, the severity of acute pancreatitis was also similar between these mice (Figure 5D-G). These observations suggest that trypsin activity also determines the severe of acute pancreatitis in patients with WT RPSS1 when the etiology factors are robust.
Increased trypsin activity was the cause of more severe pancreatitis in PRSS1<sup>R122H</sup> mice.

In vitro biochemical studies have shown that gain-of-function PRSS1 mutations increase trypsinogen auto-activation and/or inhibit trypsinogen degradation (20, 27). The mutations in the PRSS1 gene may also cause trypsinogen protein misfolding, resulting in ER stress (43). To study the nature of the R122H mutation in the development of HP, we developed another transgenic mouse line using the same construct as the PRSS1<sup>R122H</sup> mice, but they express an enzymatically dead PRSS1<sup>R122H</sup> (Dead-PRSS1<sup>R122H</sup> or PRSS1<sup>Dead</sup>). The Dead-PRSS1<sup>R122H</sup> construct was developed using genetic recombineering technology to introduce an S200T point mutation into the PRSS1<sup>R122H</sup> construct (Figure 6A), which disrupts the catalytic triad of trypsin thus abolishing its enzymatic activity (44). PRSS1 protein expression levels were similar in each of the transgenic mouse lines (Supplemental Figure 6A). Measurement of total trypsin capacity after activating trypsinogen in the pancreas lysate with enteropeptidase showed that trypsin capacity was increased by nearly 2 folds in PRSS1<sup>R122H</sup> and PRSS1<sup>WT</sup> mice (Supplemental Figure 6B). However, the trypsin capacity in Dead-PRSS1<sup>R122H</sup> mice was similar to that of C57BL/6 mice (Supplemental Figure 6B), suggesting that transgenic expression of Dead-PRSS1<sup>R122H</sup> did not increase trypsin activity levels in these mice. In consistent with these findings, cerulein increased more trypsin activity in PRSS1<sup>R122H</sup> mice but not in Dead-PRSS1<sup>R122H</sup> mice (Figure 6B). To investigate the effects of Dead-PRSS1<sup>R122H</sup> expression on the severity of pancreatitis, AP was induced by injections of cerulein (Figure 6C). Compared to the severe pancreatitis observed in PRSS1<sup>R122H</sup> mice, the Dead-PRSS1<sup>R122H</sup> mice showed only mild inflammation, which is similar to WT mice (Figure 6D-H), indicating that enzymatically dead PRSS1<sup>R122H</sup> completely abolished the severe pancreatitis caused by the PRSS1-R122H mutation. Furthermore, 7 days after cerulein induction of AP (Figure 6I) all PRSS1<sup>R122H</sup> mice developed CP (Figure 6J-L) with pancreatic atrophy (Figure 6, J and K) and chronic inflammation (Figure 6L). In stark contrast, the pancreas size and histologic findings in the Dead-PRSS1<sup>R122H</sup> mice were normal (Figure 6, J-L). Collectively, these results strongly support the idea that the R122H mutation of PRSS1 causes severe pancreatitis through increased trypsin activity, not through ER stress due to protein misfolding. The
ER stress signaling observed in the PRSS1^{R122H} mice is likely related to increased trypsin activity, as shown previously (38). The importance of trypsin in pancreatitis was also supported by other transgenic mouse models, even though the mutations of trypsinoogen used in those models are not present in human HP (38, 45).

An experimental therapeutic study with PRSS1^{R122H} mice discovered a novel therapy for hereditary pancreatitis.

Currently there are no targeted preventive or therapeutic interventions for pancreatitis. Our newly established “humanized” model of pancreatitis may offer the opportunity for preclinical evaluation of novel therapies. Because our studies have shown that trypsin activity has a critical role in the pathogenesis of pancreatitis, we aimed to test the effects of trypsin inhibition on the severity of pancreatitis. We chose to test a specific trypsin inhibitor, camostat mesylate (trypsin $K_i$ 37 nM, thrombin $K_i$ 570 nM), which has been used to treat CP in Japan (Foipan; Ono Pharmaceutical Co, Ltd) but has not been approved for use in the United States. We also included the anticoagulant dabigatran (Pradaxa; Boehringer Ingelheim Pharmaceuticals, Inc), which is primarily used as a thrombin inhibitor ($K_i$ 4.5 nM) but also inhibits trypsin activity ($K_i$ 50 nM). After initiation of AP by 5 hourly injections of cerulein, camostat or dabigatran was introduced and administered twice daily over a period of 7 days (Figure 7A). This strategy mimics a therapeutic scenario in the clinic since it typically takes a few hours after the onset of pancreatitis for patients to reach a hospital and start treatment. In untreated controls, pancreata shrank and showed histologic manifestations of CP. Camostat moderately protected the pancreas from CP at higher doses (Figure 7B-D). Surprisingly, dabigatran nearly completely abolished the progression of CP (Fig 7B-D), outperforming the more selective and stronger-affinity trypsin inhibitor camostat. We reasoned that the anticoagulation properties of dabigatran may contribute to its beneficial effects on reducing the severity of pancreatitis.

In the clinic, some AP patients may be diagnosed late. To investigate whether dabigatran will still be effective in these cases, we performed an experimental therapeutic study 20 hours after cerulein induction. Our data showed that dabigatran administration preserved the pancreas as compared to
untreated mice but to a lesser extent than those treated from 5 hours after cerulein (Supplemental Figure 7), suggesting a timely treatment is important for maximum efficacy.

A majority of AP patients do not harbor PRSS1 mutations. To examine whether dabigatran will be able to prevent the development of AP in mice with WT PRSS1, we tested the effects of dabigatran in PRSS1WT transgenic mice. Dabigatran treatment successfully prevented the development of AP in PRSS1WT mice (Supplemental Figure 8); suggesting dabigatran is not selective for mutant PRSS1 and its beneficiary therapeutic benefit can be extended to encompass a variety of AP patients.

**Anti-coagulation and trypsin inhibition synergistically improved pancreatitis.**

The existence of extensive cross-talk between coagulation and inflammation pathways has long been recognized (46). Inflammation can upregulate coagulation factors and cause hypercoagulation (47). Conversely, coagulation factor complexes stimulate protease activated receptor signaling, which induces the release of inflammatory cytokines and has important roles in pancreatitis and many other inflammatory diseases (48-52). Therefore, the reciprocal interactions between coagulation and inflammation may form a positive feedback loop that can result in progressive tissue damage (53). Consistent with this mechanism, in our animal model we also observed increased fibrin deposition (Figure 8A) in the intercellular spaces and active thrombin expression (Figure 8B), indications of activated coagulation in the pancreas. Yet, clinical trials using anticoagulation drugs alone resulted in only limited benefits (54, 55). It is likely that both trypsin and coagulation are fundamental mechanisms in the progression of CP and must be targeted simultaneously for the best effect.

To test this hypothesis we used the trypsin-specific inhibitor camostat, as well as a Factor Xa–specific anticoagulation agent apixaban (Eliquis; Bristol-Myers Squibb Company) (Ki for Factor Xa 0.25 nM, trypsin >20,000 nM), either alone or in combination (Figure 8C). As shown in Figure 8D-F, camostat and apixaban alone provided limited protection against pancreatitis; however, the combination of these 2 inhibitors significantly improved pancreatitis in these mice. The synergistic effects of antitrypsin combined with anticoagulation therapy were further validated using camostat in combination with 2 other specific anticoagulants (Supplemental Figure 9). Collectively, the data
suggests that targeting both trypsin and coagulation pathways is required for effective pancreatitis therapy.
Discussion:

In this study, we generated several transgenic mice to express human WT PRSS1 and its mutant derivatives. Mice with human hereditary pancreatitis-related PRSS1\textsuperscript{R122H} gene expression developed severe acute pancreatitis which progressed to chronic pancreatitis, recapitulating the pathogenesis of human HP. Increased trypsin activity is the key mechanism that makes PRSS1\textsuperscript{R122H} mice more susceptible to pancreatitis. With this “humanized” model of pancreatitis, we further demonstrated that coagulation plays an important role in the pathogenesis of HP. Inhibition of both trypsin and coagulation, using FDA-approved drugs for other diseases, was able to synergistically prevent the progression of chronic pancreatitis. This clinically relevant mouse model and findings obtained from this study will be informative for immediate clinical trials, encourage the further investigation into its mechanisms, and aid in the development and testing of more effective therapies for human pancreatitis.

Although AP is the most common gastrointestinal diagnosis, HP is relative rare. It is estimate that the prevalence of HP in the United States was about 1000 cases, although the actual numbers are not known (https://www.pancreapedia.org/reviews/hereditary-pancreatitis). However, patients with the mutations have >80% penetrance of developing recurrent acute pancreatitis and chronic pancreatitis with high risk of pancreatic cancer. Notably, medications that are effective for hereditary pancreatitis also work for pancreatitis with WT PRSS1. Therefore, these animal models with human PRSS1 expression can be a prototype for general pancreatitis research.

There are practical difficulties associated with obtaining biopsies from the pancreas during early stages of pancreatitis; therefore, our research into the pathophysiology of HP has been greatly limited. An animal model that recapitulates the human disease will provide us with a powerful tool to study its initiation and progression as well as interventions to treat it. Sadly, since the discovery that mutations in the PRSS1 gene were linked to the development of HP in 1996 (19, 20, 22, 23), many previous attempts to develop such an animal model by mimicking the mutations harbored in HP patients only led to limited success (26, 27). Therefore, a more sophisticated transgene strategy is required to model this disease.
Based on our experience with genetically engineered mouse models and our recent understanding of the biochemical characteristics of PRSS1, we reasoned that three major obstacles previously hindered the successful development of this model. First, the introduction of human PRSS1-equivalent mutations to the mouse form of trypsinogen will not mimic the biochemical phenotype observed in human PRSS1 mutations because of their different autoactivation properties and dissimilar regulation by chymotrypsin C (26-28). Therefore, human PRSS1, instead of mouse Prss1, should be used for transgenic expression. Second, the pancreas is specialized in synthesizing large quantities of digestive enzymes, including PRSS1. Previously, a short elastase gene promoter (≈500 bp), which lacks many regulatory components, was commonly used to drive the transgenic expression of PRSS1; however it usually gives very low and unstable transgenic expression, as we and others have observed (56, 57). Third, the regulatory mechanisms of the PRSS1 promoter are not expected to be the same as those of the elastase gene. Therefore, the native PRSS1 promoter should be used for tight regulation of PRSS1 expression. To solve all these problems in one construct, we introduced the R122H mutation into a human bacterial artificial chromosome (BAC) harboring the full-length human PRSS1 gene with an intact PRSS1 full-length promoter, all exons and introns, and the 3′-untranslated region for faithful replication of its expression as in humans. With this strategy, transgenic mice expressed the human hereditary pancreatitis-related gene PRSS1^{R122H} and developed severe acute pancreatitis which progressed to chronic pancreatitis, recapitulating many characteristics of the human disease. By comparing with transgenic mice expressing WT PRSS1 and Dead-PRSS1^{R122H}, we established that it is the R122H mutation of PRSS1 which makes the pancreas more susceptible to the development of severe pancreatitis and it is the increased trypsin activity, instead of mutation-caused protein misfolding, that we believe is the root cause of HP. Active trypsin may cause pancreatic acinar cell death through increased ER stress, oxidative DNA damage, upregulated DNA damage signaling and p53-mediated cell apoptosis.

At present, there is no proven pharmacologic entity to treat AP. Supportive care with intravenous (IV) fluids, bowel rest and pain control are the mainstays of therapy. The management of chronic pancreatitis (CP) is extremely challenging, and most patients remain symptomatic with pain,
malnutrition and diabetes despite therapy. There are no effective procedures to stop the progression or reverse these symptoms (6). Despite the strong experimental evidence showing that trypsin is a key initiator of AP (58-60), more than 70 clinical trials performed over the past 40 years have provided no definitive proof that protease inhibitors alter the course of AP (61, 62). A likely explanation for this inconsistency is that other fundamental mechanisms implicated in the progression of pancreatitis have yet to be discovered.

In recent years, it has been recognized that there is extensive cross-talk between coagulation and inflammation pathways (46, 63). Activation of one system may amplify activation of the other. Inflammation causes endothelial damage, increased fibrinogen concentration and tissue factor expression on the cell surface of leucocytes, upregulates both platelet count and platelet reactivity, and downregulates anti-coagulation factors (47). Conversely, the tissue factor/VIIa complex stimulates PAR-2 signaling, which induces release of inflammatory cytokines (48, 49). With the exception of coagulation, factor Xa and thrombin (factor IIa) are also involved in inflammation predominantly mediated via the activation of proteinase activated receptors (PAR). PAR-1, -3 and -4 are thrombin receptors. PAR-1 and PAR-2 can be activated by the TF–factor VIIa complex and factor Xa (50). PAR activation plays important roles in pancreatitis and other inflammatory diseases (51, 52). Therefore, reciprocal interaction between coagulation and inflammation forms a positive feedback loop which may result in tissue damage or even lethal multi-organ failure—a condition frequently observed in severe AP. Indeed, coagulation abnormalities were observed in AP and are related to its severity (53). In our animal models, we observed increased active thrombin and fibrin deposition in the intercellular spaces, suggesting abnormal activation of coagulation. Yet, despite the observations that coagulation may play a role in the development of pancreatitis, clinical trials using anticoagulation drugs alone resulted in only limited benefits (54, 55).

In an experimental therapeutic endeavor, we used our severe R122H pancreatitis mouse model to evaluate the preventive and therapeutic significance of several compounds which inhibit the activity of trypsin. These compounds include Camostat which is a selective trypsin inhibitor (trypsin Ki 37nM, thrombin Ki 570nM), and Dabigatran which is primarily a thrombin inhibitor (Ki 4.5nM), but also
exerts the ability to inhibit trypsin activity (Ki 50nM). In a therapeutic study each of the drugs was administered once following the last dose of caerulein then mice were given each of the drugs for an additional 6 days. Interestingly, Dabigatran which inhibits both trypsin and coagulation, showed a superior therapeutic potential compared to camostat which only inhibits trypsin. These data suggests that targeting both trypsin inhibition and anti-coagulation may be required for effective AP therapy. This hypothesis was strongly supported by the findings that the combination of the trypsin specific inhibitor and anti-coagulation specific agents can synergistically improve pancreatitis and prevent its progression to chronic pancreatitis. The underlying mechanisms of coagulation pathways in pancreatitis pathogenesis deserve more extensive and intensive investigation in future studies.

In summary, we developed a mouse model that recapitulates the histologic features of human HP. This clinically relevant mouse model and the findings obtained from this study provide justification for clinical trials with the agents studied here.
Methods

**Genetically engineered mice**

In a human bacterial artificial chromosome (BAC) (clone RP11-701D14, from BACPAC Resources, UCSF Benioff Children’s Hospital, Oakland, CA) harboring the full-length human PRSS1 gene with an intact PRSS1 full-length promoter, all exons and introns, and the 3′-untranslated region, an R122H point mutation (PRSS1$^{R122H}$) was introduced by 2 rounds of genetic targeting using GalK-mediated recombineering (Figure 1A) (29). Briefly, a prokaryotic expression em7-GalK cassette was PCR amplified from plasmid pGalK with R122 GalK F (CCGCATCCAGGTGAGACTGGGAGAGCACAACATCGAAGTCCTGGAGGGGAATGAGCAGTTCA TCACCTGTGGACAAATATCATCGGCA) and R122 GalK R (CGCCAGAGCTCGCAGTGTTGCCCCAGCCAGAGATGAGGCACTTCGTGCCAGTGCGCTGGAGG GCCGTCAGCAGCTGTCCGTGCCCTT), which contain GalK-specific sequences (underlined) and human PRSS1 homologous sequences of exon 3 (italics). The PCR product was introduced into the SW102 strain of Escherichia coli harboring the PRSS1 BAC by electroporation. Successful insertion of the GalK gene into the BAC by recombination was selected using GalK-positive selection medium and further verified by PCR (29). The PRSS1 exon 3 with the R122H mutation was PCR amplified from a cDNA plasmid with primers R122 cassette F (TGCCCTGCCCATCAGCCGCATCCAGGTGAGACTG) and R122 cassette R (GACTAAGGGTCCACCTCAGCAGCGAGGCTCGCAGTGTG). The PCR product was used to replace the GalK gene in exon 3 and introduce the R122H mutation. Positive clones were selected using GalK counter-selection medium, which eliminates GalK-positive clones. Successful introduction of R122H was verified by DNA sequencing.

The Dead-R122H construct was developed using similar GalK-mediated recombineering technology to introduce an S200T point mutation into the PRSS1$^{R122H}$ construct. The S200T mutation disrupts the trypsin catalytic triad of PRSS1 and thus abolishes its activity (64). The primers used to introduce the GalK gene to exon 5 of BAC-R122H were S200T GalK F (GCTATATTCTCTCCATCTCCTCCATACAAACTTGTCCTCTTCTTCCCCCAGGGTGACCTGTTGA
CAATTAATCATCGGCA) and S200T GalK R
(GCCATCACCCCAGGAGACAACTCCTTGGAGCTGTCCATTGCAGACCACAGGGCCACCTCAGCA
CTGTCCCTGCTCCTT) (homologous arms are in italics and GalK primers are underlined). The S200T mutation was generated with overlapping PCR primers in which TCT (coding Serine) was replaced with ACT (coding Threonine): S200T F (GTAGCTATATTCCCTCCATCTCTCCATAACAATTTGTCCCTTCTTCCCCCCCAGGGTGAT₃
CTGGTGCCCTGTGGTCTGC) and S200T R (CAGCCATCACCCCAGGAGACAACTCCTTGGAGCTGTCCATTGCAGACCACAGGGCCACCA
AG₃ATCACCCTGGGGGGAAGAAG).

Transgenic mice were developed by pronuclear injection of the BAC clones. Positive transgenes were genotyped by PCR with primers R122 Veri F (CTGTCCATGAGCAGAGCTTGAG) and R122 Veri R (CAGTGCAGAGTCTGTGTGTAATG). All the mice were maintained in 12-hour light/12-hour dark cycles with free access to food and water. Sex- and age-matched mice were used in control and experimental groups. Mice, ages 2-8 month old, were used in the experiments unless otherwise specified in the figure legend. No phenotypic differences between sex and ages were noticed in the experiments.

Cerulein-induced AP model

Cerulein-induced AP models were developed as previously described, with modification (34). Briefly, cerulein (Cat: CCKS-001; CPC Scientific, CA, USA) was dissolved in normal saline and administered by intraperitoneal (IP) injections at a dose of 50 μg/kg per injection. Twenty-four hours after the first cerulein injection, mice were sacrificed and blood was collected for measurement of serum amylase levels. The pancreas was harvested for the determination of pancreas wet weight-to-body weight ratio as a measure of pancreatic edema or pancreas size.

Experimental therapeutic study

CP was induced by 6 hourly intraperitoneal injections of 50 μg/kg cerulein on the first day (34). Seven days after the cerulein injections, mice were humanely euthanized via CO₂ inhalation and the pancreas was harvested for histologic and immunohistochemical analysis. For therapeutic studies,
mice were randomly assigned into groups and treated by oral administration with vehicle (25% Captisol in Normal Saline; Cat: RC-0C7-K01; Ligand Pharmaceuticals Incorporated, San Diego, CA, USA) or camostat mesylate (Cat: sc-203867; Santa Cruz, CA, USA), dabigatran etexilate mesylate (Cat: D100150; Toronto research chemicals, Ontario, Canada), apixaban (Cat: QC-7598-001; Combi blocks), Rivaroxaban (Cat: QA-2934-001; Combi blocks), or by intraperitoneal injection with Argatroban (Cat: A769000; Toronto research chemicals). Drug treatment began 5 hours after the first cerulein injection, twice daily over 7 days. Twelve hours after the final dose, mice were humanely euthanized and pancreata were harvested for analysis.

**L-Arginine-induced AP model**

L-Arginine-induced AP models were developed as previously described (65). Briefly, a sterile 8% (w/v) solution of L-arginine was prepared in normal saline and the pH was adjusted to 7.0; it was then administered intraperitoneally to mice at 4 g/kg (twice, at time 0 and 1 hour later). Seventy-two hours after the first L-arginine injection, mice were humanely euthanized and pancreata were harvested for analysis.

**Real-time qPCR**

Total RNA was extracted from mouse pancreas (30-40 mg tissue) using the RNeasy Plus Mini Kit (Qiagen, CA, USA). RNA (1 μg) was reverse transcribed to complementary DNA using the Go Script RT kit (Cat: A5003; Promega, WI, USA). qPCR was done using PowerUp SYBR Green Master Mix (Cat: A25742; Applied Biosystems, TX, USA). Primer information is included in Supplemental Table 1.

**Trypsin activity assay**

Trypsin activity was assessed using the trypsin activity colorimetric assay kit (Cat: ab102531; Abcam, MA, USA) according to the manufacturer’s instructions. Briefly, small pieces of tissue (40-50 mg) were homogenized in 1 mL trypsin assay buffer and centrifuged at 13,000×g for 10 minutes at 4°C. The total protein concentration of the supernatant was measured by BCA analysis, which was then used for the trypsin activity test.
**Serum amylase activity**

Serum amylase activity was measured in an aliquot of 10 μL serum from each mouse using the Phadebas amylase test (Pharmacia Diagnostics, NJ, USA) according to the manufacturer’s instructions. Mixed arteriovenous blood was centrifuged at 1,500×g for 10 minutes at 4°C. After centrifugation, the plasma was used for measurement of amylase.

**Western blot**

Total pancreatic lysates were prepared by homogenizing the pancreata in SDS-containing sample buffer. Lysates were subjected to SDS-PAGE and transferred onto a PVDF membrane. The blots were incubated with primary antibodies and processed using standard protocols. The anti-PRSS1 rabbit polyclonal antibody (Cat: AP10735c; 1:1000) was purchased from Abgent (CA, USA). The anti-GAPDH rabbit polyclonal antibody (Cat: G8795; 1:5000) was obtained from Sigma (MO, USA). The anti-BAX rabbit polyclonal (Cat: 2772s; 1:1000), anti-phospho-Histone H2A.X (Ser139) (20E3) rabbit monoclonal (Cat: 9718s; 1:1000), anti-phospho-Chk1 (Ser345) (133D3) rabbit monoclonal (Cat: 2348s; 1:1000), CHOP (L63F7) mouse monoclonal (Cat: 2895; 1:1000), and Bip (C50B12) rabbit monoclonal (Cat: 3177; 1:1000) antibodies were purchased from Cell Signaling (MA, USA). The anti-Thrombin rabbit polyclonal (Cat: ab83981; 1:500) and anti-p53 rabbit polyclonal (Cat: ab31333; 1:500) antibodies were purchased from Abcam (MA, USA).

**Histologic analysis**

Pancreas tissue was fixed in 10% neutral buffered formalin, embedded in paraffin, sectioned into 4-μm thick sections, and stained with hematoxylin-eosin. Histology scores were evaluated in a blind manner (Supplemental Table 2).

**Immunohistochemistry**

Formalin-fixed, paraffin-embedded pancreas tissue was sectioned at 4-μm thickness. Immunohistochemical staining was performed on the Dako Autostainer System (Agilent) according to the manufacturer’s instructions. The anti-CD11b (EPR1344) rabbit monoclonal (Cat: ab133357; 1:2000), anti-p53 rabbit polyclonal (Cat: ab31333; 1:400), anti-p65 rabbit polyclonal (Cat: ab16502; 1:400), anti-Fibrinogen rabbit polyclonal (Cat: ab34269; 1:1000) antibodies were purchased from...
Abcam (MA, USA). The anti-F4/80 (BM8) rat monoclonal (Cat: sc-52664; 1:250), 8-OHdG rabbit polyclonal (Cat: sc-139586; 1:80) antibodies were obtained from Santa Cruz (Santa Cruz, CA, USA). The anti-Gr-1 (RB6-8C5) rat monoclonal (Cat: 14-5931-82; 1:100) antibody was purchased from Thermo Fisher Scientific (Waltham, MA, USA). The anti-cleaved Caspase 3 rabbit polyclonal (Cat: 9661s; 1:500) antibody was obtained from Cell Signaling (MA, USA).

**TUNEL assay**

Formalin-fixed, paraffin-embedded pancreas tissue sections (4-μm thick) were deparaffinized and rehydrated. After permeabilization with proteinase K solution, the tissue was refixed with formalin and equilibrated with the equilibration buffer. Then, sections were incubated for TUNEL staining using the DeadEnd Fluorometric TUNEL System (Cat: G3250; Promega, WI, USA). Next, sections were mounted and counterstained with VECTASHIELD + DAPI (Cat: H-1200; Vector Lab, CA, USA) for 15 minutes at room temperature. Sections incubated with rTdT incubation buffer (without rTdT enzyme) were used as the negative controls and sections treated with DNase I were used as the positive controls.

**Morphologic analysis**

All measurements were performed using Image-Pro Plus Ver. 7.0.1 software (Media Cybernetics). Histologic evaluation of pancreas tissue was assessed on consecutive microscopic fields. Data were averaged and the results were expressed as the number of intranuclear positive areas per field.

**Statistical analysis.**

All data were expressed as mean ± SEM. Calculations were performed using GraphPad Prism 6.0 (GraphPad, La Jolla, CA). Two-tailed unpaired Student's t-test was used for comparisons between two groups. One-way or two-way ANOVA was used for multiple group comparisons, and significant differences between the groups were assessed using Tukey's multiple-comparisons test. Statistical significance levels are indicated as: * P < 0.05; ** P < 0.01; and *** P < 0.001.

**Study approval**

All animal experiments were approved by the Institutional Animal Care and Use Committee (IACUC) at Mayo Clinic.
Figures and Legends:

Figure 1. Transgenic expression of human PRSS1\textsuperscript{R122H} in mice. (A) Schema of generation of the transgenic human PRSS1\textsuperscript{R122H} mouse model. An R122H mutation was introduced into a bacterial artificial chromosome (BAC) harboring the full-length human PRSSI gene by GalK-mediated recombineering technology. (B) Sanger DNA sequencing confirmed a CGC>CAC mutation which confers R122H mutation. (C) Western blot showed a high level of PRSS1\textsuperscript{R122H} expression in the pancreas of transgenic mice and no expression in wild-type C57BL/6J mice. Human pancreas lysate was used as a control. Representative blots from three independent assays were shown. (D) Higher and prolonged trypsin activity was observed in the pancreatic acinar cells isolated from transgenic PRSS1\textsuperscript{R122H} mice than from C57BL/6J mice. mean ± SEM (n = 3). **P < .01, ***P < .001, n.s., not significant; two-way ANOVA with Tukey's multiple-comparisons test.
Figure 2. Transgenic expression of human PRSS1<sup>R122H</sup> caused severe acute pancreatitis.

(A) Schema of cerulein-induced acute pancreatitis protocol. (B) Representative photos of pancreata from transgenic human PRSS1<sup>R122H</sup> mice and C57BL/6J mice 24 h post cerulein induction (n = 8). (C) Significant increase in pancreatic edema (pancreas-to-body weight ratio) in PRSS1<sup>R122H</sup> mice 24 h after cerulein induction. mean ± SEM (n = 8). *P<.05, ***P<.001; two-way ANOVA with Tukey's test. (D) Serum amylase levels after 24 h of cerulein induction. mean ± SEM (n = 8). ***P<.001; two-
way ANOVA with Tukey's test. (E) Representative images of hematoxylin-eosin staining of the pancreata (n = 8). Scale bar, 300 μm. (F) Histology score evaluation of AP. mean ± SEM (n = 8). ***P<.001; two-way ANOVA with Tukey's test. (G) Representative immunohistochemical staining for CD11b (pan leukocytes), F4/80 (macrophage), and Gr-1 (neutrophil) positive inflammatory cells (brown signal with hematoxylin purple counterstain) on sections from transgenic PRSS1<sup>R122H</sup> mice and C57BL/6J mice 24 h after cerulein induction (n=8). Scale bar, 200 μm. (H) Immunohistochemical staining for analysis of p65 nuclear translocation, an indicator of NF-κB activation in the pancreata of PRSS1<sup>R122H</sup> mice and C57BL/6J mice (n = 8). Scale bar, 200 μm. (I) Quantification of p65 nuclear translocation in the pancreata of PRSS1<sup>R122H</sup> mice and C57BL/6J mice. mean ± SEM (n = 8). ***P<.001; two-way ANOVA with Tukey's test. (J) Pancreatic mRNA expression levels of monocyte chemoattractant protein-1 (Mcp1), Tumor Necrosis Factor alpha (Tnfa), interleukin 1β (Il1b), and Il6 in PRSS1<sup>R122H</sup> mice and C57BL/6J mice were measured by Real-time RT-PCR. mean ± SEM (n = 4). *P<.05, **P<.01, ***P<.001; two-way ANOVA with Tukey's test.
Figure 3. Progressive pancreatic damages and activation of stress signaling pathways in
**PRSS1**<sup>R122H</sup> **mice.** (A) Hematoxylin-eosin staining showed progressive pancreatic damages on sections from transgenic PRSS1<sup>R122H</sup> mice after cerulein-induced acute pancreatitis. In contrast, similarly treated C57BL/6J mice recovered fully (representative of 5 independent samples). Scale bar, 400 μm. (B) Acinar cell death, pancreatic edema, and inflammation evaluation in AP after cerulein induction. mean ± SEM (n = 5). **P < .01, ***P < .001, n.s., not significant; two-tailed unpaired Student's t-test. (C) Using TUNEL staining, extensive pancreatic acinar cell apoptosis was detected in transgenic PRSS1<sup>R122H</sup> mice after cerulein induction. In contrast, pancreatic acinar cell apoptosis in C57BL/6J mice was much less prevalent (representative of 5 independent samples). Scale bar, 200 μm. (D) Cleaved caspase 3 was upregulated in the pancreatic acinar cells of PRSS1<sup>R122H</sup> mice (representative of 5 independent samples). Scale bar, 200 μm. (E) Western blot showed higher levels of p53 and its target gene BAX, DNA damage signaling p-CHK1, and abnormal ER stress-related proteins Bip and CHOP in the pancreata of PRSS1<sup>R122H</sup> mice than in C57BL/6J mice. Representative blots from three independent assays were shown. (F) Immunohistochemical staining for 8-hydroxy-2'-deoxyguanosine (8-OH) and phospho-Histone H2A.X (Ser139) (p-H2A.X) indicated the presence of DNA damage in the pancreata of PRSS1<sup>R122H</sup> mice. Representative of 5 independent samples. Scale bar, 200 μm. (G) mRNA levels of endoplasmic reticulum stress-related signaling molecules *Atf4* (activating transcription factor 4) and *Xbp1s* (X-box binding protein 1spliced), and reactive oxygen species (ROS)-related enzymes *Duox1* (Dual oxidase 1) and *Gpx4* (Glutathione peroxidase 4) were measured by real time RT-PCR. mean ± SEM (n = 4). **P<.01, ***P<.001, n.s., not significant; two-way ANOVA with Tukey's multiple-comparisons test.
Figure 4. Chronic pancreatitis developed in transgenic PRSS1^{R122H} mice. (A) Schema of cerulein administration protocol. (B) After cerulein induction, the body weight changes of the mice were monitored. mean ± SEM (n = 5-10). (C) Representative pancreas images on day 70 from transgenic PRSS1^{R122H} mice and wild-type C57BL/6J mice (n = 5-10). (D) Pancreas weight was compared 70 days after cerulein induction. mean ± SEM (n = 5-10). ***P<.001; two-tailed unpaired Student’s t-test. (E) Chronic pancreatitis with fat replacement, fibrosis, and pancreatic intraepithelial neoplasia (PanIN) lesions developed in PRSS1^{R122H} mice. These features were similarly observed in the pancreata of human patients with hereditary pancreatitis. (F) Overall histology score of chronic pancreatitis. mean ± SEM (n = 5-10). ***P<.001; two-tailed unpaired Student’s t-test.
Figure 5. PRSS1\textsuperscript{R122H} mice were more sensitive to induction of pancreatitis than PRSS1\textsuperscript{WT} mice. (A) Transgenic mice expressing wild-type human PRSS1 (PRSS1\textsuperscript{WT}) were generated to compare with PRSS1\textsuperscript{R122H} mice. (B) Western blot showed similar expression levels of PRSS1 in these transgenic mice. Representative blots from three independent assays were shown. (C) Pancreatic acinar cells were isolated from the indicated mice and trypsinogen activation in response to low and high concentrations of CCK was measured. mean ± SEM (n = 3). **P < .01, ***P < .001, n.s., not significant; one-way ANOVA with Tukey's multiple-comparisons test. (D) Greater pancreatic edema (pancreas-to-body weight ratio) was seen in PRSS1\textsuperscript{R122H} mice compared with PRSS1\textsuperscript{WT} mice at 24 h after a single-dose of cerulein. The cerulein dose ranged from 2.5-50 µg/kg. mean ± SEM (n = 5). *P < .05, **P < .01, ***P < .001; one-way ANOVA with Tukey's multiple-comparisons test. (E) Greater serum amylase levels were seen in PRSS1\textsuperscript{R122H} mice than in PRSS1\textsuperscript{WT} mice. mean ± SEM (n = 5). *P < .05, **P < .01, ***P < .001; one-way ANOVA with Tukey's multiple-comparisons test. (F) Overall histology score of AP developed after various doses of cerulein insults. mean ± SEM (n = 5). **P < .01, ***P < .001, n.s. not significant; one-way ANOVA with Tukey's multiple-comparisons test. (G) Representative Hematoxylin-eosin (H&E) staining showed that PRSS1\textsuperscript{R122H} mice were more sensitive to cerulein-induced acute pancreatitis than PRSS1\textsuperscript{WT} mice (n = 5). Scale bar, 200 µm.
Figure 6. Increased trypsin activity was the cause of severe pancreatitis in PRSS1<sup>R122H</sup> mice.

(A) Enzymatically inactive Dead-PRSS1<sup>R122H</sup> (PRSS1<sup>Dead</sup>) transgene construct was developed by introducing a S200T point mutation into PRSS1<sup>R122H</sup> using recombineering technology. (B) In response to cerulein, Dead-PRSS1<sup>R122H</sup> generated same amount of active trypsin as C57BL/6 mice. mean ± SEM (n = 3). ***P < .001; one-way ANOVA with Tukey's test. (C) Schema of cerulein-induced acute pancreatitis in PRSS1<sup>Dead</sup> and PRSS1<sup>R122H</sup> mice. (D) Enlarged pancreata was observed in PRSS1<sup>R122H</sup> mice but not in PRSS1<sup>Dead</sup> mice 24 h after cerulein induction (n = 10). (E) Comparison of pancreatic edema (pancreas-to-body weight ratio) 24 h after cerulein induction. mean ± SEM (n = 10). ***P < .001; two-tailed unpaired Student's t-test. (F) Comparison of serum amylase level 24 h after cerulein induction. mean ± SEM (n = 10). ***P < .001; two-tailed unpaired Student's t-test. (G)
Cerulein caused more severe acute pancreatitis in PRSS1\textsuperscript{R122H} mice than in PRSS1\textsuperscript{Dead} mice. Representative images of H&E staining 24 h after cerulein induction were shown (n = 10). Scale bar, 200 μm. (H) Overall histology score of AP from PRSS1\textsuperscript{R122H} mice and PRSS1\textsuperscript{Dead} mice. mean ± SEM (n = 10). ***$P<.001$; two-tailed unpaired Student's $t$-test. (I) To investigate cerulein-induced chronic pancreatitis in PRSS1\textsuperscript{R122H} and PRSS1\textsuperscript{Dead} mice, the mice were sacrificed 7 days after cerulein induction. (J) Seven days after cerulein induction, all the pancreata from PRSS1\textsuperscript{R122H} mice shrank (indicating chronic pancreatitis), but all the pancreata from PRSS1\textsuperscript{Dead} mice appeared to be normal (n = 8). (K) The pancreas-to-body weight ratio 7 days after cerulein indicated that the pancreas in PRSS1\textsuperscript{R122H} mice was much smaller than in PRSS1\textsuperscript{Dead} mice. mean ± SEM (n = 8). ***$P<.001$; two-tailed unpaired Student's $t$-test. (L) At day 7, histologic examination (H&E staining) demonstrated chronic damages in PRSS1\textsuperscript{R122H} mice, whereas the pancreata of PRSS1\textsuperscript{Dead} mice were normal (n = 8). Scale bar, 200 μm.
Figure 7. Effective experimental therapeutics with an FDA-approved anticoagulation agent in PRSS1\textsuperscript{R122H} mice. (A) Schema of pancreatitis induction and treatment in PRSS1\textsuperscript{R122H} mice: Pancreatitis was induced by cerulein, and therapeutic drugs were administered 5 hours after the first cerulein injection. (B) After 7 days of treatment, pancreata in the untreated control group became smaller. In contrast, pancreata in dabigatran-treated groups were mostly normal. Camostat only exhibited intermediate effects at higher doses (300 mg/kg). Both drugs were given twice daily for 7 days. mean ± SEM (n = 10 per group). ***P<.001; one-way ANOVA with Tukey's multiple-comparisons test. (C) Histology score evaluation showed that dabigatran significantly improved CP. mean ± SEM (n = 10 per group). ***P<.001; one-way ANOVA with Tukey's multiple-comparisons test. (D) Representative images of hematoxylin-eosin (H&E) staining after drug treatments over 7 days (n = 10 per group). Scale bar, 200 μm.
Figure 8. Anticoagulation and trypsin inhibition synergistically improved pancreatitis in PRSS1<sup>R122H</sup> mice. (A) Immunohistochemical analysis showed intrapancreatic fibrin deposition, an indicator of increased coagulation, in the pancreata of PRSS1<sup>R122H</sup> mice 24 hours after cerulein induction (n = 5). Scale bar, 200 μm. (B) Western blot showed that active thrombin significantly increased in the pancreata of PRSS1<sup>R122H</sup> mice compared with C57BL/6J mice. Representative blots from three independent experiments are shown. (C) Schema of pancreatitis induction and drug treatment with the anticoagulation specific agent (apixaban), trypsin specific inhibitor (camostat), or in combination. 5 hours after pancreatitis induction, drugs were given twice daily by oral gavage over 7 days. (D) Combination of anticoagulation therapy with factor Xa inhibitor apixaban (100 mg/kg) and trypsin inhibitor camostat (200 mg/kg) greatly protected the pancreas, as manifested by preservation
of pancreas mass. mean ± SEM (n = 15 per group). ***P<.001; one-way ANOVA with Tukey's multiple-comparisons test. (E) Representative histologic images of H&E staining from untreated, apixaban alone, camostat alone, and combination therapy–treated mice (n = 15 per group). Scale bar, 200 μm. (F) Overall histology score evaluation of the mice. mean ± SEM. Representative results from six mice per group were shown. ***P<.001; one-way ANOVA with Tukey's multiple-comparisons test.
Author Contributions:

FG, YZ, JW coordinated the project and were involved in most experiments including data collection and statistical analysis. The authorship order of the co–first authors was assigned based on their relative contributions. BJ, FG and AH drafted the manuscript. FG, YZ, YL, JG, YW performed in vitro assays. FG, YZ, JW, XZ, JS, YY, JC, XZ performed in vivo assays. BE embedded and processed the tissues, H&E and IHC staining. LZ performed pathologic analysis. BJ generated and characterized the transgenic mice. YB and BJ discovered the new use of Dabigatran in pancreatitis therapy, supervised the study, finalized the manuscript, and secured funding support.
