The mechanisms underlying rapid elimination of herpes simplex virus-2 (HSV-2) in the human genital tract despite low CD8+ and CD4+ tissue-resident T cell (Trm cell) density are unknown. We analyzed shedding episodes during chronic HSV-2 infection; viral clearance always predominated within 24 hours of detection even when viral load exceeded 1 × 107 HSV DNA copies, and surges in granzyme B and IFN-γ occurred within the early hours after reactivation and correlated with local viral load. We next developed an agent-based mathematical model of an HSV-2 genital ulcer to integrate mechanistic observations of Trm cells in situ proliferation, trafficking, cytolytic effects, and cytokine alarm signaling from murine studies with viral kinetics, histopathology, and lesion size data from humans. A sufficiently high density of HSV-2–specific Trm cells predicted rapid elimination of infected cells, but our data suggest that such Trm cell densities are relatively uncommon in infected tissues. At lower, more commonly observed Trm cell densities, Trm cells must initiate a rapidly diffusing, polyfunctional cytokine response with activation of bystander T cells in order to eliminate a majority of infected cells and eradicate briskly spreading HSV-2 infection.

Introduction

CD8+ and CD4+ tissue-resident T cells (Trm cells) rapidly identify and control recurrent human viral infections within peripheral sites (1–11). Trm cells lodge preferentially at prior sites of pathogen replication without recirculating in blood and are differentiated from circulating memory T cells based on microanatomic localization, cell-surface markers, and transcriptional profile (5, 12–15). During herpes simplex virus-2 (HSV-2) infection in humans, CD8+ T cells with Trm cell characteristics cluster at the dermal-epidermal junction, where neuron endings release HSV-2 into the mucosa (9, 10, 16). The heterogeneous spatial aggregation of Trm cells in genital skin explains the considerable variability of HSV-2 severity, including episodes that are contained after a few hours of viral replication and those that persist for many days and cause symptomatic lesions (17–21).

Recent murine studies employing intravital imaging describe the extraordinary range of Trm cell control mechanisms in situ. In the absence of antigen, Trm cells efficiently survey previously infected tissues to recognize and eliminate infected cells during reactivation (1, 22). During this immunosurveillance phase, Trm cells express dendrite-like arms to contact a large number of potentially infected cells (1, 22) and remain in an activated state despite the absence of antigen-driven stimulus via the T cell receptor (8). Upon recognition of an infected cell, Trm cell motility is restricted and abundant local proliferation ensues (22). Trm cells then mediate efficient, contact-mediated apoptosis of infected cells by releasing perforin and granzyme B (23–25).

Upon activation, Trm cells induce a broad antiviral program consisting of cytokine release and resultant generalized local inflammation (1, 8). Cytokines, notably IFN-γ, may induce clearance of HSV-2 infection (26, 27) and render surrounding cells resistant to infection, even with unrelated pathogens (1). Chemokines such as CXCL9 and CXCL10 may draw local immune cells to infected sites (11, 28). Cytokines and chemokines diffuse rapidly, are efficiently internalized by their target cells (29), and exert paracrine effects upon cells that are not in direct contact with Trm cells.

Analysis of human biopsy specimens of HSV-2–infected tissues reveals high-density clusters of both CD8+ and CD4+ Trm cells in certain microregions, with low densities of Trm cells in others (20). Yet a majority of HSV-2 shedding episodes are eliminated within 6 to 24 hours (19, 21, 30). Because individual HSV-2 ulcers are small, this rapid peak in viral load is more likely due to an intense local immune response rather than target cell limitation (19, 30–32).

It is unknown how low numbers of Trm cells orchestrate elimination of infected cells so efficiently. Different mechanisms may mediate elimination of a few infected cells over hours during mild episodes versus thousands of infected cells over days during more severe episodes. Here, we construct an agent-based mathematical model to recapitulate the spatiotemporal dynamics underlying the
viral spread, cytokine expansion, and Trm cell-mediated containment of HSV-2 in genital tissues.

Results

**Intense immune pressure within 24 hours of HSV-2 detection.** A characteristic of HSV-2 shedding episodes in chronically infected persons is rapid viral expansion, followed by a slightly more protracted clearance phase (21, 33, 34). Although most episodes share this core feature, they vary in severity. Many asymptomatic episodes are cleared in 6 to 12 hours and peak at less than 10^4 HSV DNA copies. Other episodes exceed 10^7 HSV DNA copies and are associated with visible lesions and shedding over days to weeks (30, 35, 36). In episodes longer than 4 days, longevity is driven by a rebound of HSV after an initial phase of clearance, likely due to seeding of new ulcers in immunologically distinct environments, we reanalyzed 83 episodes (655 total swabs from 20 subjects) from a data set in which study participants performed swabs every 6 hours over 60 days. We binned episodes by duration into short (<1 day), medium (1-2 days), and long (>2 days) (30) and identified brisk viral expansion with an early peak in all episodes, even those with high viral loads (Figure 1A). There was a wide distribution of viral loads of the first episode peak (Figure 1B), ranging from 2.2 to 7.9 log_{10} HSV DNA copies. Episodes were of variable duration, but elimination usually occurred in less than 48 hours, with a minority lasting over 100 hours (Figure 1C). Median time to the first viral load peak was 7 hours; all episodes reached their first peak within 20 hours (Figure 1D). Moderate correlations were noted between time to first peak and first peak viral load (Figure 1E) and time to first peak and duration (Figure 1F). Symptoms tended to occur during episodes with the highest first viral load peak (Figure 1B) and of the longest duration (Figure 1C). Within symptomatic episodes, symptoms usually coincided with the highest local viral loads (Figure 1A).

These results confirm that massive HSV-2 replication is a defining early feature of shedding episodes. However, immunologic responses predominate — usually within 10 hours of viral detection and always within 20 — and time of the initial peak predicts severity. Whether an episode progresses to high viral loads and days of shedding or rapid containment in the first several hours may depend on the intensity of the immune response during the early hours of reactivation.

**Heterogeneous dispersion of CD8+ and CD4+ Trm cells in HSV-2-infected genital tissues.** HSV-2 reactivates in specific microenvironments throughout the human genital tract because of random traveling of virions along highly arborized branches of peripheral neurons (37). We previously observed a fixed spatial metastructure of CD8+ and CD4+ T cell density in infected tissue, defined by dense clusters in some regions and low numbers in others (20). To characterize tissue microenvironments, we summarized Trm cell densities observed in 18 genital biopsy specimens (Figure 2A) performed at 2 and 8 weeks following lesion healing (we refer to all observed T cells as Trm cells, though it is possible that a minority are not truly resident). We divided each image into regions, with 100 cells per region (Figure 2, B and C) and calculated the ratio of Trm cells to epithelial cells (in situ effector/target [E:T] ratio) for CD8+ Trm cells, CD4+ Trm cells, and both subsets combined.

We then created a rank-order distribution of all observed ratios (Figure 2D). For CD8+ Trm cells, the median E:T ratio in the 779 microregions was 0.01 (IQR, 0–0.05; range, 0–1.58). For CD4+ Trm cells, the median E:T ratio in the 779 microregions was 0 (IQR, 0–0.01; range, 0–0.29). CD8+ Trm cells outnumbered CD4+ Trm cells in both 2 and 8 weeks after lesion healing (Figure 2D). The median E:T ratio was 0.02 (IQR, 0–0.07; range, 0–3.4) for CD8+ and CD4+ Trm cells combined. CD8+, CD4+, and both classes of Trm cells were absent in 37.1%, 60.7%, and 29.8% of the microregions (E:T = 0), respectively. E:T ratios for the 18 specimens ranged from 0.01 to 0.24 (median = 0.03) for CD8+ Trm cells and from 0 to 0.03 (median = 0.01) for CD4+ Trm cells. For each specimen, we fit an exponential model to the rank order curve and achieved close reproduction of the data (Figure 2D and Methods). The median exponential slopes of the rank order abundance curve for all T cells was −0.121 (range, −0.222 to −0.045). Exponential slopes were similar between CD4+ (median, −0.197; range, −1.072 to −0.114) and CD8+ (median, −0.216; range, −1.77 to −0.083) Trm cells and fell within a narrow range at both 2- and 8-week time points (Figure 2D), implying that an equivalent gradient between high and low Trm cell density regions is imprinted during chronic HSV-2 infection (Figure 2, A and D). Specimens with a higher proportion of microregions with E:T = 0 had lower overall E:T ratios (Figure 2E).

**A mathematical model of HSV-2 replication and spread within a single ulcer.** We next sought to explain how infected cells are eliminated quickly, given the low Trm cell densities commonly observed in infected samples. To approximate spatial conditions of a single-infection microenvironment, we developed a 2D stochastic, agent-based mathematical model. Our goal was to precisely link spatial heterogeneity of Trm cell density (Figure 2) with observed heterogeneity in shedding episode kinetics (Figure 1). We developed the model in an iterative fashion to limit required parameter fitting at each step.

First, we simulated HSV-2 replication and spread, assuming no Trm cell immunity (Figure 3A; see Methods for details and Supplemental Table 1 for model parameters; supplemental material available online with this article; https://doi.org/10.1172/JCI132583DS1), to recapitulate early HSV-2 shedding episode kinetics. The agent-based model assumes that HSV-2 replication occurs in a 2-stage process within an infected cell. Newly infected cells enter a preproductive phase, during which immediate-early and early viral proteins are expressed, but HSV DNA replication has yet to occur (38). After several hours, HSV DNA polymerase activity initiates, leading to production of infectious viral particles for approximately 20 hours until cell lysis and death (Figure 3A).

Human HSV-2 infection occurs within nucleated epithelial cells in genital skin or mucosa. The 3D anatomy of this tissue space consists of approximately 2 to 10 stacked epidermal cells between the surface of the skin and the dermal-epidermal junction where HSV-2 is released from nerve endings. For simplicity, our model is made of a 2D lattice consisting of tightly packed square cells with 8 potential cellular contacts at edges and corners: this assumption is in accordance with the arrangement of squamous epithelial cells within tissue. Many cells in the top lay-
Figure 1. Early and intense immunological pressure against HSV-2 replication within genital microenvironments. (A) Three HSV-2 shedding episodes with typical characteristics, including rapid time to first peak viral load and rapid viral clearance. Red circles indicate symptomatic time points. (B–D) Analysis of 83 shedding episodes derived from every 6-hour genital sampling. Box plots with IQR (box) and 1.5 × IQR (whiskers). Categorization according to duration: short, under 24 hours (n = 51); medium, 24 to 48 hours (n = 13); and long, over 48 hours (n = 19). (B) Variable first peak viral loads and (C) durations across episodes, with most episodes eliminated in fewer than 48 hours. (D) Uniform occurrence of first peak viral load within the first 20 hours of HSV-2 detection. (E) Correlation of time to first peak viral load with peak episode viral load (Spearman’s = 0.434, P < 0.001). (F) Correlation of time to first peak viral load with episode duration (Spearman’s = 0.534, P < 0.001). (B–F) Red dots indicate symptomatic episodes, which tend to be longer and associated with higher first peak viral loads.
severely compromised T cell immunity due to HIV/AIDS or stem cell transplantation (42). Our basic model recapitulates untreated HSV-2 infection in these clinical populations.

A mathematical model incorporating Trm cell trafficking, dendritic, local proliferation, and rapid contact-mediated killing of infected cells. Most immunocompetent persons start to clear each HSV-2 shedding episode within a day after viral load peaks (Figure 1). To capture this fact, we added Trm cell immunity to the baseline model (Methods and Supplemental Table 2). For each simulated episode, we generated varying realistic densities of CD8+ and CD4+ Trm cells across the modeled grid based on our analysis of biopsy specimens (Figure 2), by randomly sampling from exponential model reproductions of Trm cell abundance (Figure 2D and Methods). A relatively low percentage of CD8+ T cells from genital lesions (range, 1%-10%) were specific for HSV-2, though this was contingent upon recognition of a single preselected HLA-restricted HSV epitope (9, 43). These percentages are low bounds for the actual total percentages of CD8+ T cells that are specific to HSV-2, given that multiple HSV epitopes are likely to induce HSV-specific T cell responses. To represent conditions favoring the local immune system, we used a higher percentage (40%) of Trm cells retaining the ability to recognize HSV-2 antigen and kill adjacent infected cells in a contact-dependent manner.

Numerous recent murine studies allow parameterization of Trm cell behavior in tissue during the immunosurveillance phase between HSV-2 shedding episodes. When cognate antigen is not present, Trm cells patrol the cellular grid (Figure 5A and ref. 44). Recent evidence provides rates for Trm cell movement and suggests that trafficking follows a random walk over time scales of hours (1, 22). Patrolling Trm cells project dendritic arms to achieve a greater number of contacts with adjacent cells (Figure 5A and refs. 1, 22). We selected a value for Trm cell dendriticity that captures the average number of target cells that a single Trm cell touches at a given point in time.

HSV-2–specific Trm cells undergo phenotypic changes upon contacting and engaging an infected cell, taking on a round morphology and transiently limited mobility. Brisk in situ Trm cell proliferation ensues; in the context of a significant peptide challenge, Trm cell levels increase approximately 10-fold over a 24-hour period in some models, though this is likely a high estimate (Figure 5A and refs. 23, 24). With the goal of again simulating conditions favoring local immunity, we included in situ proliferation at this high rate in our model.

Upon recognizing and adhering to an infected cell, Trm cells induce apoptosis within 30 minutes, presumably via secretion of granzyme B and perforin (Figure 5A and ref. 25). In our simulations, Trm cells occupy sites on the grid of epidermal cells. If Trm cells are at sites adjacent to (via a corner or edge) or in the same location as an infected cell, they can kill these infected cells via TCR contact-mediated mechanisms at a fixed rate or in a synergistic fashion, such that an infected cell contacted by several T cells dies more rapidly (Methods and ref. 25). We also assume that a single T cell can concurrently kill multiple adjacent infected cells via dendritic extensions (45). Cytokine paracrine effects against infected cells were not included in this version of the model.

Unimpeded HSV-2 spread in the presence of Trm cells that exert contact-mediated killing but no paracrine effects. When we simulated the model with the above assumptions of Trm cell immunosurveil-

ers of human skin are not permissive to HSV replication, so lateral cell-to-cell spread of HSV-2 is more efficient than apical-to-basal spread (39). Nevertheless, by neglecting the vertical dimension of cells, the model may underestimate total number of infected cells and viral load.

To approximate the observation that infection of adjacent cells occurs via tight junctions (40), we allowed individual viruses to diffuse with random directionality across the grid immediately after their production. Viruses that resided in the same model region as susceptible cells generated infection with a concentration-dependent probability at each time step (Methods).

Unimpeded HSV-2 spread in the absence of Trm cells. In simulations without Trm cells, viral load expanded rapidly during the first 12 to 18 hours of infection (Figure 3B) but reached maximal values slightly lower than those observed during the most severe shedding episodes (Figure 1, A and B). This discrepancy may be due to our model’s 2D structure of cells. Another probable explanation is that the empirical data often include the sum of viral contributions to diffuse with random directionality across the grid immediately after their production. Viruses that resided in the same model region as susceptible cells generated infection with a concentration-dependent probability at each time step (Methods).

A mathematical model incorporating Trm cell trafficking, dendritic, local proliferation, and rapid contact-mediated killing of infected cells. Most immunocompetent persons start to clear each HSV-2 shedding episode within a day after viral load peaks (Figure 1). To capture this fact, we added Trm cell immunity to the baseline model (Methods and Supplemental Table 2). For each simulated episode, we generated varying realistic densities of CD8+ and CD4+ Trm cells across the modeled grid based on our analysis of biopsy specimens (Figure 2), by randomly sampling from exponential model reproductions of Trm cell abundance (Figure 2D and Methods). A relatively low percentage of CD8+ T cells from genital lesions (range, 1%-10%) were specific for HSV-2, though this was contingent upon recognition of a single preselected HLA-restricted HSV epitope (9, 43). These percentages are low bounds for the actual total percentages of CD8+ T cells that are specific to HSV-2, given that multiple HSV epitopes are likely to induce HSV-specific T cell responses. To represent conditions favoring the local immune system, we used a higher percentage (40%) of Trm cells retaining the ability to recognize HSV-2 antigen and kill adjacent infected cells in a contact-dependent manner.

Numerous recent murine studies allow parameterization of Trm cell behavior in tissue during the immunosurveillance phase between HSV-2 shedding episodes. When cognate antigen is not present, Trm cells patrol the cellular grid (Figure 5A and ref. 44). Recent evidence provides rates for Trm cell movement and suggests that trafficking follows a random walk over time scales of hours (1, 22). Patrolling Trm cells project dendritic arms to achieve a greater number of contacts with adjacent cells (Figure 5A and refs. 1, 22). We selected a value for Trm cell dendriticity that captures the average number of target cells that a single Trm cell touches at a given point in time.

HSV-2–specific Trm cells undergo phenotypic changes upon contacting and engaging an infected cell, taking on a round morphology and transiently limited mobility. Brisk in situ Trm cell proliferation ensues; in the context of a significant peptide challenge, Trm cell levels increase approximately 10-fold over a 24-hour period in some models, though this is likely a high estimate (Figure 5A and refs. 23, 24). With the goal of again simulating conditions favoring local immunity, we included in situ proliferation at this high rate in our model.

HSV-2–specific Trm cells undergo phenotypic changes upon contacting and engaging an infected cell, taking on a round morphology and transiently limited mobility. Brisk in situ Trm cell proliferation ensues; in the context of a significant peptide challenge, Trm cell levels increase approximately 10-fold over a 24-hour period in some models, though this is likely a high estimate (Figure 5A and refs. 23, 24). With the goal of again simulating conditions favoring local immunity, we included in situ proliferation at this high rate in our model.

Upon recognizing and adhering to an infected cell, Trm cells induce apoptosis within 30 minutes, presumably via secretion of granzyme B and perforin (Figure 5A and ref. 25). In our simulations, Trm cells occupy sites on the grid of epidermal cells. If Trm cells are at sites adjacent to (via a corner or edge) or in the same location as an infected cell, they can kill these infected cells via TCR contact-mediated mechanisms at a fixed rate or in a synergistic fashion, such that an infected cell contacted by several T cells dies more rapidly (Methods and ref. 25). We also assume that a single T cell can concurrently kill multiple adjacent infected cells via dendritic extensions (45). Cytokine paracrine effects against infected cells were not included in this version of the model.

Unimpeded HSV-2 spread in the presence of Trm cells that exert contact-mediated killing but no paracrine effects. When we simulated the model with the above assumptions of Trm cell immunosurveil-

ers of human skin are not permissive to HSV replication, so lateral cell-to-cell spread of HSV-2 is more efficient than apical-to-basal spread (39). Nevertheless, by neglecting the vertical dimension of cells, the model may underestimate total number of infected cells and viral load.

To approximate the observation that infection of adjacent cells occurs via tight junctions (40), we allowed individual viruses to diffuse with random directionality across the grid immediately after their production. Viruses that resided in the same model region as susceptible cells generated infection with a concentration-dependent probability at each time step (Methods).

Figure 2. Heterogeneous dispersion of CD8+ T and CD4+ cells within HSV-2–infected genital biopsy specimens obtained after lesion healing. Analysis of 18 genital biopsy specimens from 10 participants 2 weeks (n = 9) or 8 weeks (n = 9) after lesion healing. (A) Three-color RGB image with cell nuclei (blue), CD4+ T cells (green), and CD8+ T cells (red) of a 2-week specimen. (B) 100-Cell microregions designated according to clusters shown as separate colors; - , cluster center. (C) CD8+ (triangles) and CD4+ T cells (squares) within each microregion. (D) Rank order distributions of effector/target (E:T) ratios within microregions. E:T ratios from each cluster are ranked according to size. Lines indicate single specimens; wide ranges of E:T ratios within each specimen indicate clustering of T cells in high-density regions and multiple regions with no T cells. Similar rank order slopes indicate a fixed gradient of T cell density across specimens (described in Results). (E) High variability of whole specimen E:T ratios (x axis) across 2- and 8-week specimens; inverse correlation of whole specimen E:T ratios with the proportion of 100 cell regions containing no CD8+ (red triangles) or CD4+ (blue squares) T cells (y axis).

A 2D structure of uncontrolled infection emerged from the model (Supplemental Video 1). The leading edge of simulated ulcers consisted of preproductive, newly infected cells surrounding a thicker band of productively infected cells and a central core of dead and regenerating cells (Figure 4A). An outer ring of high viral load overlying productively infected cells was noted after 2 days (Figure 4B), with a far outer ring of lower viral load due to viral diffusion. The asymptotic behavior of viral load relates to spatial features of the mathematical model: target cell limitation promotes the average number of target cells that a single Trm cell contacts at a given point in time.

HSV-2–specific Trm cells undergo phenotypic changes upon contacting and engaging an infected cell, taking on a round morphology and transiently limited mobility. Brisk in situ Trm cell proliferation ensues; in the context of a significant peptide challenge, Trm cell levels increase approximately 10-fold over a 24-hour period in some models, though this is likely a high estimate (Figure 5A and refs. 23, 24). With the goal of again simulating conditions favoring local immunity, we included in situ proliferation at this high rate in our model.

Upon recognizing and adhering to an infected cell, Trm cells induce apoptosis within 30 minutes, presumably via secretion of granzyme B and perforin (Figure 5A and ref. 25). In our simulations, Trm cells occupy sites on the grid of epidermal cells. If Trm cells are at sites adjacent to (via a corner or edge) or in the same location as an infected cell, they can kill these infected cells via TCR contact-mediated mechanisms at a fixed rate or in a synergistic fashion, such that an infected cell contacted by several T cells dies more rapidly (Methods and ref. 25). We also assume that a single T cell can concurrently kill multiple adjacent infected cells via dendritic extensions (45). Cytokine paracrine effects against infected cells were not included in this version of the model.

Unimpeded HSV-2 spread in the presence of Trm cells that exert contact-mediated killing but no paracrine effects. When we simulated the model with the above assumptions of Trm cell immunosurveill-
lance and pathogen containment, there was insufficient immunologic pressure to eliminate all infected cells. We simulated 100 episodes at 10 realistic E:T ratios (range, 0.013–0.13). Asymptotic viral shedding was observed in all cases (Figure 5B). E:T ratio was predictive of viral load set point in these simulations (Figure 5C), indicating that contact-mediated killing by Trm cells exerts immunologic pressure. We next simulated 100 episodes at extremely high E:T ratios (>0.20) rarely observed in our specimens (Figure 2E): only 21% were associated with viral elimination by 3 days, whereas the remaining episodes demonstrated persistent shedding at high viral copy number. We concluded that only very rarely does contact-mediated killing by Trm cells generate enough immunologic pressure to achieve local viral containment.

A spatial approximation of this infection model demonstrates that more infected cells are killed by Trm cells than direct viral lysis (Supplemental Video 2 and Figure 6A) and that viral loads are lower per cellular region over time (Supplemental Video 2 and Figure 6B), relative to simulations without Trm cells (Supplemental Video 1 and Figure 4B). Nevertheless, HSV-2 spreads effectively through microregions of both low and high Trm cell density (Supplemental Video 3 and Figure 6C). We conclude that, despite the addition of multiple optimized Trm cell functions to our model, including highest possible rates of in situ killing, proliferation, and HSV-2 specificity, HSV-2 spread outpaces direct cell-to-cell killing via Trm cells and completely fails to recapitulate observed shedding episode features in immunocompetent humans (Figure 1A). This observation led us to include non–contact-mediated functions of Trm cells in our model.

Secretion of granzyme B and IFN-γ early during human HSV-2 shedding episodes. To validate inclusion of cytokines in our mathematical model, we performed local sampling for cytokine quantitation every 3 hours during naturally occurring shedding episodes in persons with chronic HSV-2 infection. During all episodes, we noted an early 1- to 2-log surge in granzyme B (Figure 7A), compatible with direct contact-mediated killing of infected cells by local T cells and NK cells. We detected an increase of similar magnitude in IFN-γ concordant with episode peaks (Figure 7A), suggesting that Trm cells exert paracrine effects. Because CD8+ and CD4+ T cells outnumber NK cells in HSV-2 lesions at the dermal-epidermal junction (16), these cells are likely to be critical producers of both detectable granzyme B and IFN-γ, though we cannot rule out contribution from NK cells in the dermis. Keratinocyte-derived cytokines, including IFN-α and IFN-β, did not consistently surge to comparably high levels during these episodes and were often absent or present at significantly lower levels (Figure 7A). Furthermore, across all samples (Figure 7B) and, in particular, in samples from the single largest lesion ulcer (Figure 7C), viral load
showed a much stronger correlation with T cell–associated cytokines (granzyme B and IFN-γ) compared with epithelial-derived cytokines (IFN-α and IFN-β). Moreover, levels of granzyme B and IFN-γ were highly correlated, particularly from single-ulcer samples (Figure 7, B and C).

Model refinements to assess possible cytokine mechanisms for containment of local HSV-2 infection. Trm cell–secreted cytokines may generate a local alarm state via numerous paracrine mechanisms after diffusing across a field of cells. We updated our model to include 4 possible but unproven cytokine functions: (a) enhanced elimination of infected cells, (b) reduction in viral replication rate, (c) reduction in HSV-2 infectivity, and (d) induction of bystander (non–HSV specific) Trm cell proliferation and cytokine production (Figure 8A). Inclusion of these mechanisms as possibly relevant is experimentally justified based on in vitro and murine work: at minimum, the presence of IFN-γ is required for elimination of HSV spread and lowering viral titers in epithelial cells (26, 46); local production of IFN-γ has a powerful impact on gene expression within epithelial cells and other antigen-presenting cells (APCs) (47–49) and renders keratinocytes resistant to HSV-2 infection for several days in mice (2); Trm cell–derived cytokines, particularly IFN-γ, induce apoptosis in HSV-2–infected fibroblasts (27), though similar experiments in epithelial cells are lacking; finally, cytokines may stimulate proliferation, differentiation, and innate-like cytokine secretion from other local bystander CD8+ T cells in a paracrine fashion (49–53).

Because it is unknown which of these mechanisms is relevant during human infection, we generated 16 models with every possible combination, including a model lacking any cytokine functionality (Figure 5A) and one with all 4 functions. For all models, we assumed that bystander Trm cells are incapable of recognizing and lysing infected cells via direct contact. CD4+ T cells were included in the model, but assumed to lack direct killing ability based on lack of MHC-I expression, and therefore served as bystander cells that proliferate and contribute to the cytokine alarm system (53).

We imputed experimentally observed values of cytokine production by activated Trm cells into the model (Supplemental Table 3). The rate of cytokine diffusion across a cellular scaffold was estimated in vitro (29), and exceeded that of viral cell-to-cell spread. Given that rates of cellular uptake and diffusion of cytokines in vivo are unknown, we varied these 2 parameters across wide ranges of values for all models tested. For models including one or more of the mechanisms described above, we varied additional parameters. For instance, we included values
clinical protocol, we assumed sampling every 6 hours and random episode initiation 0 to 6 hours after each simulated sample.

We explored 500 possible randomly selected parameter sets for the 16 models. For each unique parameter set, we simulated 125 episodes, each with different initial conditions of Trm cell density drawn randomly from exponential models of rank-order distributions (Figure 2D). Given the stochastic nature of the model, we then used the best parameter set and performed 100 additional simulations to arrive at a range of model and parameter set–specific fitting scores. In total, we simulated 16,000,000 HSV-2 ulcers to identify an optimal model.

Recapitulation of shedding episode kinetics with incorporation of HSV-2–specific Trm cell cytokine secretion into the mathematical model. To identify which cytokine functions and parameters best recapitulate the observed data, we performed comparative model fitting to shedding episode data using Akaike information criteria (AIC) to reward for fit while penalizing for unnecessary complexity. We fit to shedding data from the 83 episodes described in Figure 1. Episodes were arrayed in rank abundance curves according to first peak viral load, duration, and time to first peak, such that the models were tasked with reproducing the entire distribution of shedding episode severity (Supplemental Figure 1). To mimic the clinical protocol, we assumed sampling every 6 hours and random episode initiation 0 to 6 hours after each simulated sample.

Models with no cytokine activity fit poorly to the data, as virus was rarely eliminated (Figures 5 and 6 and Supplemental Figure 1A). Addition of a single cytokine mechanism improved fit only if the mechanism was increasing infected cell death rate or, to a lesser extent, lowering viral replication rate. Four models outperformed all other models by a significant degree, and each included a minimum of 2 cytokine mechanisms: increasing infected cell death rate and activation of bystander Trm cells (Figure 8A and Supplemental Figure 1A). A model with all 4 cytokine mechanisms gave the lowest median AIC scores over 100 runs; however, there was substantial run-to-run variability for a given model and parameter values due to the stochastic nature of the model (Supplemental Figure 1A). Based on overlapping AIC scores over 100 runs, decreased viral infectivity and lower HSV-2 replication rate cannot be formally ruled in or out as operative cytokine mechanisms during infection. Inclusion of these 2 mechanisms resulted in more realistically shaped round (rather than serpiginous) ulcers, and therefore they were kept in the model for all subsequent videos and figures.

![Figure 5. Failed elimination of infected cells in mathematical model simulations in which Trm cells only exert contact mediated killing.](image-url)
We added a fifth possible mechanism, cytokine induction of a chemical gradient to allow T cells to home to sites of infection; this did not alter the simulated data and was not subsequently included. Similarly, adjusting modes of Trm cell trafficking from random walk to Levy walk did not alter model fit and was not subsequently included. These results suggest that elimination of HSV-2–infected cells by cytokines involves at least 2 complementary mechanisms.

Finally, when we simulated the model with the assumption that only CD8+ Trm cells (and not CD4+ T cells, which lie deeper in the dermis) can contribute to local viral containment, we achieved only slightly worse median fit compared with the model inclusive of both cell populations (Supplemental Figure 1A). We are therefore unable to parse out the relative contributions of these 2 cellular populations.

The optimized model slightly overestimated distributions of episode first peak viral load and durations at moderate ranks (Supplemental Figure 1, B and C) and substantially underestimated first peak viral load and duration of the most severe episodes (Supplemental Figure 1, B and C) but closely recapitulated distribution of time to first episode peak (Supplemental Figure 1D). The model accepted a wide range of plausible values for rates of cytokine uptake into cells and viral diffusion. A narrower range was identified for cytokine diffusion rate, indicating the importance of this value for model fitting. Threshold upper limits were identified for necessary intracellular concentration of cytokines to limit viral replication and induce death in infected cells, prevent infection in uninfected cells, and activate surrounding Trm cells. These values were low, suggesting that cells are extremely sensitive to these proteins (Supplemental Table 3).

Rapid containment of infection under low Trm cell conditions due to rapid cytokine diffusion derived from HSV-2–specific Trm cells. Viral load trajectories in simulated episodes were notable for early peaks, rapid expansion rate, and short duration (Figure 8B); timing of cytokine surge (Figure 8B) was comparable to human shedding episodes (Figure 7A). As with murine studies (24), E:T ratio in the infected area was fairly predictive of first peak viral load in simulations; this was true when a field of 15,625 or 49 target cells was considered (Figure 8, C and D). A Trm cell-to–epithelial cell ratio of greater than 0.2
within the 49 target cell field was predictive of rapid elimination of HSV-2-infected cells before development of viral loads sufficient for lesion development and sexual transmission potential (>10^4 HSV DNA copies) (Figure 8D); this exceeded ratios observed in most human biopsy specimens (Figure 2E). Early recognition of infection by Trm cells often resulted in elimination of virus in 6 to 24 hours with fewer than 20 total infected cells (Supplemental Video 4).

Spatial visualization demonstrates that, during more severe episodes, later initial recognition of an infected cell by an HSV-2–specific Trm cell (due to a lower Trm cell density) is followed by rapid diffusion of cytokines and immediate impact of cytokine antiviral effects (Figure 9 and Supplemental Videos 5 and 6). Accordingly, in simulations, both cellular distance between the initial infected cell and the nearest HSV-2–specific CD8+ T cell (Figure 10A) and time between infection of the first cell and recognition of an infected cell by an HSV-2–specific Trm cell (Figure 10B) were highly predictive of first peak viral load. Time to antigen recognition also was predictive of total number of infected cells (Figure 10C) and local shedding duration (Figure 10D). As episodes increased in severity, the proportion of infected cells killed by cytokine effects rather than direct lysis by Trm cells was generally higher (Figure 10E). For episodes contained to 5 or fewer cells, 100% were mediated by Trm cell–mediated contact killing alone without the need for cytokine functionality.

Trm cell density determines extent of episodes with higher numbers of initially infected cells. We previously demonstrated that prolonged episodes are likely due to sequential seeding of new ulcers in new microenvironments and that the cumulative viral load of severe episodes consists of viral production from numerous contemporaneous infection microenvironments (19). However, it is less certain whether the rapid wave of cytokines would limit additional viral production if multiple viral seeding events occurred within a single simulated microenvironment. To test for this effect, we simulated 1000 episodes with random selection of E:T ratio and varying numbers of initial numbers of infected cells within the 15,625 cells. Decreasing E:T ratios below 0.15 and, to a lesser extent, increasing the number of infectious plaques allowed higher first peak viral loads and numbers of infected cells (Supplemental Figure 2). This result may partially explain why our model fitting underestimated the highest viral load when starting with a single infected cell (Supplemental Figure 1B). However, viral seeding of immunologically distinct microenvironments, which occurs during human infection, is not captured in our model and is a more likely explanation for episodes extending beyond 3 days (Supplemental Figure 1C).
Limited effects on HSV-2 elimination due to Trm cell trafficking, dendriticy, proliferation, and cooperative killing. We performed additional in silico knockout experiments to identify the relative importance of non–cytokine-mediated Trm cell mechanisms of immune control. Surprisingly, elimination of Trm cell dendriticy, mobility, or proliferation resulted in very little change in the overall proportion of episodes with higher first peak viral load (Supplemental Video 4A), longer duration including persistence at 6 days (Supplemental Video 4B), longer time to first peak viral load (Supplemental Video 4C), and higher total number of infected cells (Supplemental Video 4D). Among single cytokine mechanisms, activation of bystander Trm cells (particularly induction of cytokine secretion) and limitation of infected cell life span were most critical in limiting episode duration and time to first peak viral load. Simulations in which cytokines did not affect infected cell life span (Supplemental Video 7) or HSV infectivity (Supplemental Video 8) led to more protracted episodes in which ulcers took on an uncharacteristic serpiginous appearance.

T cell trafficking from blood is unlikely to explain observed HSV-2 shedding episode kinetics. In the murine system, within 72 hours of...
antigen introduction, local amplification of T cell levels is mainly via Trm cell proliferation rather than trafficking of CD8+ T cells from blood or draining lymph nodes (23, 24). In most cases of human infection, HSV-2 DNA has been eliminated from tissue at this (72-hour) time point. However, it is still possible that trafficking of effector memory T cells (Tem cells) contributes to local amplification of T cell levels soon after HSV-2 reactivation. Rapid production of proinflammatory cytokines and chemokines by epithelial cells has been shown to drive early T cell recruitment to infection sites (54).

We therefore tested the Tem cell mechanism in a model as an alternative to local Trm cell–mediated control. We assumed no Trm cells and estimated the number of HSV-2–specific T cells that would randomly passage through infected tissue per day by considering the following: the products of cardiac output, ratio of skin blood flow to total organ blood flow, ratio of genital skin to total skin, ratio of infected genital skin to total genital skin, lymphocytes per liter of blood, ratio of T cells to total lymphocytes, and ratio of HSV-2–specific T cells to total T cells in circulation (ref. 55 and Methods). Due to uncertainty and person-to-person variability in many of these values, we estimate that roughly 10 to 1000 HSV-2–specific Tem cells could arrive at a lesion per day. Although rapid trafficking of a high enough number of HSV-2–specific CD8+ T cells into infected tissue allowed for viral elimination, assuming cytokine production, this model did not produce the observed heterogeneity of episode first peak viral load, time to first peak viral load, and duration (Supplemental Figure 5), and AIC scores of the Tem cell model were well above those of the best Trm cell model. Therefore, heterogeneity in spatial density of Trm cells is a more likely explanation for the observed shedding episode data.

Discussion
Trm cells play a critical role in mucosal protection against HSV-2. During chronic infection, genital tissue contains HSV-2–specific CD4+ and CD8+ Trm cells months after local elimination of infected cells (9). The release of HSV-2 from latently infected ganglia via sensory neurons into genital tissues is temporally and spatially stochastic, resulting in seeding of low- and high-density Trm cell regions (19, 20, 56). Reactivations are initiated by infection of epithelial cells by ganglionic derived viruses, which are released from neurons in very low numbers based on the low replication rate of HSV-2.
which infection is limited to a few cells, but other episodes that persist for days and are associated with lesions, infection of thousands of epithelial cells, multiple loci of infection, and high transmission risk (59, 60).

Although HSV-2 achieves sufficient replication to induce a disease state in many infected people, we show here that the immune system wins each local battle with remarkable efficiency. Viral loads usually peak within 12 hours, and always within 24 hours, after viral DNA detection; the abrupt transition from viral expansion to contraction is associated with high levels of granzyme B and IFN-γ. Using a mathematical model, we demonstrate that during the critical early hours of reactivation when only a few cells are infected, if an HSV-2–specific Trm cell is in proximity, then it will induce rapid contact-mediated apoptosis and the episode will terminate without need for an amplified local response. If infection expands to hundreds or thousands of cells over 12 to 24 hours before Trm cell recognition and activation, then Trm cell contact–mediated killing is insufficient for pathogen control, despite efficient trafficking, expression of dendritic arms to canvas a high number of local cells, in situ proliferation, and rapid cooperative killing of infected cells.

The essential second step for truncating local shedding is cytokine secretion leading to a profound antiviral state. Secreted cytokines diffuse rapidly and are absorbed efficiently by infected keratinocytes (29). Based on best fit to observed data, our model suggests that cytokines exert at least 2 effects: rapid killing of infected cells and activation of bystander Trm cells, with possible lowering of HSV-2 replication rate and HSV-2 infectivity. Experimental evidence suggests that IFN-γ reduces HSV-2 infectivity to susceptible cells and may increase apoptosis of infected cells (26, 27). Inclusion of the latter mechanism was crucial for recapitulating early viral load peak and episode durations. Cytokines other than IFN-γ may be contributing to these effects in a synergistic manner. The rapid lethality of diffusing cytokines also explains the abrupt formation of clinical vesicles and erosions concurrent with viral clearance.

The generalized cytokine alarm state mechanism explains how HSV-2 elimination occurs rapidly within mucosal microregions defined by low HSV-specific Trm cell density (2). In our model, recognition of infected cells by a single pathogen-specific Trm cell is necessary but insufficient for initiation of tissue-wide protection. The timing of this sentinel event is the critical determinant of the extent of viral replication. We also demonstrate that episode heterogeneity is unlikely to be explained by a model in which infected cell elimination is governed primarily by circulating effector T cells. We previously demonstrated that local proliferation of Trm cells in response to HSV-2 reactivation, rather than

---

**Figure 10. Time of HSV-2 recognition by HSV-2–specific Trm cells as a determinant of local infection severity.** One thousand simulated episodes with initial E:T ratio densities randomly selected from exponential models of CD8+ and CD4+ Trm cell data shown in Figure 2D. (A) Correlation of cellular distance between nearest HSV-specific CD8+ Trm cells and first infected cell with \(\log_{10}\) peak viral load. (B–E) Correlations of time to first Trm cell recognition of an infected cell with (B) \(\log_{10}\) peak viral load, (C) total infected cells, and (D) duration. (E) Proportion of infected cells killed by cytokine effects as a function of number of total infected cells per episode. Of episodes, 20.5% involve only a single infected cell. Blue lines, LOESS-smoothed lines with 95% CI in gray.
arrival of Trm cell from blood, is also the most likely explanation for the fixed spatial structure of these cells within infection microenvironments (20).

As was demonstrated in a mouse model, the total density of HSV-2–specific Trm cells is likely to be a key surrogate of immunity (24). In a 3 mm × 3 mm simulated microregion, and even more so within a smaller 50-cell region surrounding the first infected cell, Trm cell density maintains an inverse dose response with first peak viral load and shedding duration. Therefore, to achieve full protection, a therapeutic vaccine must achieve high HSV-2–specific Trm cell levels within all microregions across the genital region. During natural infection, the number of HSV-2–specific Trm cells is only sufficient to provide rapid protection in approximately 20% of tissue (20).

Our model projects that bystander Trm cells, which cannot recognize infected cells but secrete cytokines upon activation, play an important role in late elimination of infected cells during severe episodes. Removal of cytokine-mediated bystander Trm cell activation allows a higher proportion of uncontained episodes 6 days after initiation. However, a high density of Trm cells that lack antigen specificity is not the most predictive surrogate of local immune protection. Rather, a sufficient number of HSV-2–specific CD8+ T cells close to the site of reactivation is key for local immune protection. Rather, a sufficient number of HSV-2–specific CD8+ T cells close to the site of reactivation is key for achieving near sterilizing immunity.

Our in silico knockout analysis allows a detailed assessment of the relative contribution of Trm cell phenotypic characteristics to the pace of HSV-2 elimination. Single noncytokine functions can be eliminated without dramatically impairing control of infection. Elimination of Trm cell trafficking, in situ proliferation, dendricity, or contact-mediated killing has only modest effects on viral load during simulations; however, deleting multiple functions leads to a slight increase in episode duration and first peak viral load. We conclude that most of these functions are vital for establishing an optimal environment for immunosurveillance between episodes.

Our approach has important limitations pertaining to oversimplification of the immune response. We cannot discriminate the relative per-cell potency of CD4+ and CD8+ T cell antiviral effects (28) and do not consider infiltrating NK cells. CD8+ T cells colocalize with infected cells at the dermal-epidermal junction to a greater extent than CD4+ T cells, which provide help at a distance from the dermis (16). We demonstrate that CD8+ T cells are consistently present at higher numbers than CD4+ T cells. NK cells lack antigen specificity and are present in lower abundance in healing genital specimens (8, 16). Nevertheless, both cell populations may be vital for early control of human herpes viruses, exhibit memory, and secrete IFN-γ, perforin, and granzyme B (10, 61, 62). Therefore, NK cells and CD4+ T cells may serve as bystander cells and contribute to the alarm state (8). It will be important to distinguish the role of various infiltrating immune cell subsets in future models as relevant data accrues.

We also do not explicitly model cytokine–mediated epithelial cell–induced innate immunity (46, 63, 64), APCs (65), or antibody effects (66). Although these mechanisms undoubtedly play a role in pathogen elimination, their effects may not be as variably dispersed over time and tissue space as Trm cells. Unlike IFN-γ, keratinocyte–derived IFN-α and IFN-β levels were not correlated with local viral loads. Therefore, our model may capture humoral and innate immunity effects that are embedded within static model parameters for viral replication, infectivity, and spread. In addition, we include a parameter to capture duration of T cell and infected cell contact required to induce Trm cell activation; this parameter indirectly captures the activity of APCs (67). If either of these effects vary in a nonlinear fashion relative to local viral load, or if infected epithelial cells and APCs sufficiently activate bystander Trm cells during severe episodes even in the absence of HSV-specific Trm cells, then our model misses these dynamics.

We denote cytokines as one variable in our model, which is overly reductionist. The multiple antiviral effects of IFN-γ are crucial, but a complex network of multiple cytokines is likely to influence HSV-2 containment, with varying effects according to cellular source and cellular target. Although a powerful cytokine impact on infected cells is a robust feature of our model, it currently lacks the granularity to distinguish effects of individual cytokines. A more comprehensive assessment will only be possible as new data allow detailed parameterization of individual cytokine effects on HSV-2–infected cell life span, viral replication, viral infectivity, and T cell bystander activation.

Finally, our model projections deviate from the observed data in important ways. The best-fitting model does not achieve the highest peak viral loads or durations observed in episodes, possibly because the 2D model includes fewer target cells for HSV-2 replication than human skin. Our model also only simulates a single ulcer, while swabbing protocols capture HSV-2 from multiple contemporaneous ulcers, particularly during severe high viral load episodes (19). Despite inclusion of multiple antiviral mechanisms, the optimal model slightly overestimated the distribution of episode first-peak viral loads and durations at low ranks. This may be because other infiltrating immune cell populations not included in the model contribute to control of infection. Another explanation is that our model assumes that all viruses being produced are detected with sampling, whereas in reality only cell-free viruses may be detected.

Despite these limitations, modeling provides a unique platform for linking observations from murine and human experiments, which is important because both of these approaches have inherent gaps. In humans, Trm cell responses evolve quickly within microscopic tissue environments and have not been captured during critical early stages of viral replication and spread. Successful containment of HSV-2 in a few cells is asymptomatic and even more difficult to observe empirically. Yet quantitative components of human data, including heterogeneity in shedding–episode kinetics and spatial density and topology of Trm cells, serve as critical benchmarks for model validation.

Murine models using intravital imaging allow observation and quantification of Trm cell behaviors. Indeed, these experiments inspired and informed our model (2). However, these experiments are rarely centered around realistic kinetics of pathogen control. Moreover, murine infection conditions may not be representative of human HSV-2 reactivation. It is plausible that Trm cell trafficking, dendricity, proliferation, synaptic killing, and antiviral cytokine release occur in humans and mice. Yet in vivo rates governing these behaviors may differ. Our analysis shows that knockout of some of these mechanisms results
in only small perturbations in viral shedding outcomes. As such, the models and results described here form the basis for hypotheses that may be confirmed through empirical observations from future human experiments.

Several experimental results in humans would strengthen the predictions of our model. For example, demonstration of strong upregulation of IFN-stimulated genes in uninfected cells and apoptotic signals in infected cells would be supportive. Single-cell transcriptomics may allow granular readouts of the source and impact of different cytokines expressed during and after contained local infection.

HSV-2-infected individuals experience shedding episodes that are frequent and highly variable due to the spatial distribution of Trm cells. We propose that containment of infection within low Trm cell-density areas is contingent upon rapid diffusion of antiviral cytokines afforded by antiviral cytokines to induce a spatially homogeneous layer of immunological readiness.

**Methods**

**Study design.** We reanalyzed data from a previous study where HSV-2 seropositive, HIV-negative individuals were asked to self-collect genital swab specimens 4 times a day for 60 days. Viral load was measured using quantitative PCR (qPCR) (30). For each participant, we divided the time series of viral loads into individual shedding episodes.

**Image analysis of human biopsy specimens.** We reanalyzed ×10 RGB images from previously described human HSV-2 genital biopsy specimens showing cell nuclei (blue), CD4+ T cells (green), and CD8+ T cells (red) (20). Each of 10 participants was biopsied at 2 and 8 weeks after healing of the lesions. Two samples were excluded because the neurons were too difficult to crop out. Using the 18 remaining images, we enumerated CD8+ and CD4+ T cells and total nuclei representative of T cells and epithelial cells using the program Cell Profiler (ref. 68 and Supplemental Methods).

**Cytokine data from swabs.** Four study participants with recurrent HSV lesions were enrolled in an additional protocol in which swabs were obtained every 8 hours before lesion development. At the time of prodrome or ulcer formation, participants switched to every 3 hour sampling for 5 days. Two swabs were obtained at each time point. One was processed for HSV PCR (36), and the other was sent for Meso Scale Discovery assay for cytokine quantitation (69). Data were analyzed as per sample (total genital tract viral loads, n = 326; lesion-only viral load, n = 185; total genital tract cytokines, n = 157; lesion-only cytokines, n = 112).

**Individual-based model of viral spread and immunological containment of infection by Trm cells.** We developed a stochastic, agent-based, spatially explicit model of HSV infection that incorporates key features of host and virus life cycles and immune control by CD8+ and CD4+ T cells, based on a previously developed model of host-pathogen dynamics (70). The model is described in detail in the Supplemental Methods.

**Data and materials availability.** All code and data are available at http://github.com/proychou/SpatialHSV (commit ID facf56bd0d9d-8135e073c358342ebd3549c6d98). The model is available in both R and C++ versions and can be run on multiple computing platforms.

**Statistics.** For Figure 1, correlations were performed using Spearman’s coefficient. For Figure 2, rank abundance curves were generated for projection of E:T ratios across microregions. Exponential model fitting to these distributions is described above. For Figure 5, correlations were performed between log-converted cytokine values and HSV-2 viral load using Spearman’s coefficient. A P value of less than 0.05 was considered statistically significant.

**Study approval.** Data for these studies were obtained from a previous study where HSV-2–seropositive, HIV-negative individuals were asked to self-collect genital swab specimens (30). All study subjects gave informed consent before enrollment, and the human subjects protocols were approved by the University of Washington Institutional Review Board. All clinical investigations were conducted according to the principles expressed in the Declaration of Helsinki.

**Author contributions**

PR conceived the study, performed mathematical modeling, performed statistical analyses, and wrote the manuscript. DAS performed spatial analyses of biopsy specimens, mathematical modeling, and statistical analyses. ED assisted with literature review and model parameter selection. LC conceived the biopsy study. JZ performed staining of biopsy specimens. VD and LRS performed cytokine analysis. JML and MP conceived the study and edited the manuscript. JTS conceived the study, performed mathematical modeling, performed statistical analyses, and wrote the manuscript.
