Anemia in β-thalassemia is related to ineffective erythropoiesis and reduced red cell survival. Excess free heme and accumulation of unpaired α-globin chains impose substantial oxidative stress on β-thalassemic erythroblasts and erythrocytes, impacting cell metabolism. We hypothesized that increased pyruvate kinase activity induced by mitapivat (AG-348) in the Hbb\textsuperscript{th3/+} mouse model for β-thalassemia would reduce chronic hemolysis and ineffective erythropoiesis through stimulation of red cell glycolytic metabolism. Oral mitapivat administration ameliorated ineffective erythropoiesis and anemia in Hbb\textsuperscript{th3/+} mice. Increased ATP, reduced reactive oxygen species production, and reduced markers of mitochondrial dysfunction associated with improved mitochondrial clearance suggested enhanced metabolism following mitapivat administration in β-thalassemia. The amelioration of responsiveness to erythropoietin resulted in reduced soluble erythroferrone, increased liver \textit{Hamp} expression, and diminished liver iron overload. Mitapivat reduced duodenal \textit{Dmt1} expression potentially by activating the pyruvate kinase M2-HIF2α axis, representing a mechanism additional to \textit{Hamp} in controlling iron absorption and preventing β-thalassemia–related liver iron overload. In ex vivo studies on erythroid precursors from patients with β-thalassemia, mitapivat enhanced erythropoiesis, promoted erythroid maturation, and decreased apoptosis. Overall, pyruvate kinase activation as a treatment modality for β-thalassemia in preclinical model systems had multiple beneficial effects in the erythropoietic compartment and beyond, providing a strong scientific basis for further clinical trials.
The pyruvate kinase activator mitapivat reduces hemolysis and improves anemia in a β-thalassemia mouse model

Anemia in β-thalassemia is related to ineffective erythropoiesis and reduced red cell survival. Excess free heme and accumulation of unpaired α-globin chains impose substantial oxidative stress on β-thalassemic erythroblasts and erythrocytes, impacting cell metabolism. We hypothesized that increased pyruvate kinase activity induced by mitapivat (AG-348) in the Hbbth3/+ mouse model for β-thalassemia would reduce chronic hemolysis and ineffective erythropoiesis through stimulation of red cell glycolytic metabolism. Oral mitapivat administration ameliorated ineffective erythropoiesis and anemia in Hbbth3/+ mice. Increased ATP, reduced reactive oxygen species production, and reduced markers of mitochondrial dysfunction associated with improved mitochondrial clearance suggested enhanced metabolism following mitapivat administration in β-thalassemia. The amelioration of responsiveness to erythropoietin resulted in reduced soluble erythropoietin, increased liver Hamp expression, and diminished liver iron overload. Mitapivat reduced duodenal Dmt1 expression potentially by activating the pyruvate kinase M2-HIF2α axis, representing a mechanism additional to Hamp in controlling iron absorption and preventing β-thalassemia–related liver iron overload. In ex vivo studies on erythroblast precursors from patients with β-thalassemia, mitapivat enhanced erythropoiesis, promoted erythroid maturation, and decreased apoptosis. Overall, pyruvate kinase activation as a treatment modality for β-thalassemia in preclinical model systems had multiple beneficial effects in the erythropoietic compartment and beyond, providing a strong scientific basis for further clinical trials.

Introduction

Ineffective erythropoiesis and reduced red cell survival are key determinants of the anemia and other comorbidities in β-thalassemia (1–3). Reduced β-chain production leads to a decoupling from heme production, resulting in an excess of unpaired α-globin chains and increased free heme. This process results in massive production of ROS with severe cellular oxidative damage, leading to a block in cell maturation, increased apoptosis, and ineffective erythropoiesis. In addition, increased ROS in maturing reticulocytes and erythrocytes cause hemolysis and shorten red cell survival in the peripheral circulation (4, 5).

Erythropoiesis is a metabolically demanding process: erythroid maturation strictly depends on intracellular cyclic adenosine nucleotides and ATP, and mitochondrial biogenesis plays a crucial role in ATP generation (6–9). Reduced ATP concentrations have been reported in β-thalassemic human red cells compared with healthy controls (10, 11). Abnormal mitochondrial clearance in maturing erythrocytes from hemoglobin (Hb) E/β-thalassemia patients has also been described (12).

Recently, Zhang et al. described altered gene expression of some constituents of the glycolytic pathway in murine β-thalassemic erythroid precursors, suggesting that erythrocyte metabolism and glycolysis are also affected by ineffective erythropoiesis (4). The amelioration of ineffective erythropoiesis observed in β-thalassemia mice treated with rapamycin, an mTOR inhibitor, is associated with downregulation of metabolic enzymes, including pyruvate kinase M2 (PKM2) (4). The ROS-mediated inhibition of PKM2 might redirect glucose to the pentose phosphate pathway to counteract oxidation (13, 14). Chronic oxidation overwhelms antioxidant cell capacity in β-thalassemic erythroid cells, as indicated by lower
activity of reduced glutathione (GSH) and upregulation of peroxiredoxin-2, an NADPH-dependent cytoprotective system (15–17).

Pyruvate kinase plays a key role in cell metabolism, as it mediates the final step of glycolysis that yields 2 ATP and 2 pyruvate molecules per glucose molecule. It is essential for the survival of mature red blood cells and is necessary to sustain the TCA cycle in red blood cell precursors. Four different isoforms have been described: PKL, PKR (both encoded by Pklr and expressed in liver and duodenum, or erythroid cells, respectively), PKM1, and PKM2 (both present in multiple tissues, refs. 18–20). The expression of PKM2 is inducible in response to oxidation or hypoxia, whereas PKL/PKR are expressed constitutively (18–20). Patients with pyruvate kinase deficiency, an autosomal recessive disease caused by reduced PKR activity, develop chronic hemolytic anemia associated with signs of ineffective erythropoiesis. Of note, the expression of residual PKM2 has recently been reported in a patient with pyruvate kinase deficiency, supporting the importance of pyruvate kinase for erythroid cells (21). Studies in mouse models genetically lacking PKR have shown extramedullary erythropoiesis associated with ineffective erythropoiesis, further supporting the role of PKR in erythroid maturation (22–25).

Mitapivat (AG-348) is a small-molecule activator of pyruvate kinase that binds to an allosteric pocket to stabilize the active tetrameric form and enhance its affinity for its substrate, phosphoenolpyruvate (26–28). A phase 2 clinical trial of mitapivat in adult patients with pyruvate kinase deficiency who were not receiving regular transfusions demonstrated that the molecule elicited a rapid and sustained increase in Hb levels in approximately 50% of treated patients and was generally well tolerated, with adverse events being mainly low grade and transient (26). Interim analysis of an ongoing phase 2 study of mitapivat in patients with non–transfusion-dependent thalassemia (NCT03692052) demonstrated that 92.3% (12 of 13 evaluable patients) achieved an Hb increase from baseline of ≥ 1 g/dL, including 4 of 4 patients with α-thalassemia and 8 of 9 patients with β-thalassemia (29).

We studied the effects of mitapivat in a mouse model of β-thalassemia, investigating the impact on erythropoiesis, hemolysis, anemia, iron overload, and the mechanisms involved therein. These data on the pharmacological targeting of ATP generation as a means of ameliorating β-thalassemia–associated anemia are particularly valuable for informing the development of new treatment strategies. This is especially relevant since clinical safety and tolerability for mitapivat are already available and it is currently being evaluated as a potential therapy for patients with thalassemia.

Results

Treatment with mitapivat improved anemia in a mouse model for β-thalassemia. The expression of pyruvate kinase isoforms PKR and PKM2 was evaluated in red cells from WT mice and the Hbbth3/+ mouse model of β-thalassemia, which mimics the severity of human β-thalassemia intermedia (4, 30). We analyzed red cells as a whole population or fractionated them according to cell density into 2 main fractions: fraction 1 (F1), enriched in reticulocytes; and fraction 2 (F2), containing the densest red cells and older erythrocytes (31).

The expression of both PKR and PKM2 was higher in both F1 and F2 red cells from Hbbth3/+ mice compared with WT cells (Supplementary Figure 1A; supplemental material available online with this article; https://doi.org/10.1172/JCI44206DS1). Pyruvate kinase activity was elevated in Hbbth3/+ cells compared with WT cells, consistent with the observed expression levels (Supplemental Figure 1B). As expected, ROS were markedly increased in Hbbth3/+ erythrocytes when compared with WT erythrocytes (Supplemental Figure 1C). Notably, ROS levels were higher in Hbbth3/+ F1 than in Hbbth3/+ F2, most likely because the more severely damaged red cells are rapidly removed from the peripheral circulation (31, 32).

In sorted Hbbth3/+ polychromatic and orthochromat erythroblasts, the expression of PKM2 was again increased when compared with WT mice (Supplemental Figure 1D). The increased expression of PKM2 in Hbbth3/+ erythroid cells is of particular interest: pyruvate kinase is a key enzyme in the final step of glycolysis, and upregulation of PKM2 may be a compensatory response to oxidation as observed in other cell models (33) and in a patient with pyruvate kinase deficiency (21). The importance of PKM2 expression in response to cellular stress is also supported by evidence in hematopoietic murine cells genetically lacking PKM2 (34). In β-thalassemia, the increased expression of PKM2 might be compensatory for PKR activity to ensure cell maturation when faced with oxidative stress.

We then asked whether further pharmacological activation of pyruvate kinase may be of benefit in β-thalassemia. The pyruvate kinase activator, mitapivat, was either administered by gavage (50 mg/kg twice a day) for 21 days or added to the mouse diet for 56 days to minimize the possible stress related to animal manipulation. As shown in Figure 1A, mitapivat treatment resulted in markedly improved red cell morphology compared with baseline in Hbbth3/+ mice. Hbbth3/+ smears showed typical hypochromic red cells, marked polychromasia, and various forms of fragmented erythrocytes (poikilocytes) associated with stressed erythropoiesis and hemolysis. Poikilocytosis improved visibly after 14 and 21 days of treatment with mitapivat. Hb, mean corpuscular volume (MCV), and mean corpuscular Hb (MCH) also increased in Hbbth3/+ mice after 3 weeks of mitapivat treatment (Figure 1B and Supplemental Table 1). A significant decrease in absolute reticulocyte counts was also found in mitapivat-treated Hbbth3/+ mice (P < 0.05), in conjunction with increased reticulocyte MCV (Figure 1C and Supplemental Table 1). Similar results were also observed in Hbbth3/+ mice treated with mitapivat for 56 days (Supplemental Figure 2, A and B). Consistent with these data, we also found a marked reduction in circulating erythroblasts (Supplemental Figure 2C).

The amelioration of anemia and red cell indices was associated with a significant reduction in α-globin membrane precipitates (P < 0.05) and an increase in the fraction of soluble Hb in red cells from mitapivat-treated Hbbth3/+ mice compared with vehicle-treated animals (Figure 1D). A significant decrease of ROS in circulating Hbbth3/+ erythrocytes was observed after 3 weeks of mitapivat treatment (P < 0.05; Figure 1E), which was associated with an increased GSH/glutathione disulfide (GSSG) ratio (Figure 1F). Hemichromes bound to the membrane of red cells from mitapivat-treated Hbbth3/+ mice were also significantly reduced compared with vehicle-treated animals (P < 0.05; Supplemental Figure 2D). There was a trend toward increased ATP levels in blood from treated animals (Supplemental Figure 2E), consistent with activation of pyruvate kinase. Plasma total bilirubin,
Mitapivat treatment improved chronic hemolytic anemia and red cell survival in the Hbbth3/+ mouse model of β-thalassemia. WT and Hbbth3/+ mice were treated with vehicle or mitapivat 50 mg/kg twice daily. (A) Erythrocyte morphology. One representative image from 8 with similar results shown. Original magnification ×100. (B and C) Hb, MCV, MCH, and reticulocyte count in WT and Hbbth3/+ mice treated with vehicle or mitapivat. Data are mean ± SD (n = 6). (D, left panel) Triton acid-urea gel electrophoresis of red cell membrane from WT and Hbbth3/+ mice treated with vehicle or mitapivat (21 days). Arrows show α-globin and β-globin associated with red cell membrane. (D, middle panel) Gel quantification expressed as α-globin/β-globin ratio to Hb. Data are mean ± SD (n = 6). (D, right panel) Total and soluble Hb (Drabkin’s method) in hemolysates from Hbbth3/+ mice treated with vehicle or mitapivat (21 days). Data are mean ± SD (n = 6). (E) ROS levels in red cells from WT and Hbbth3/+ mice treated with vehicle or mitapivat. Data are mean ± SD (n = 6 each). (F) Difference in the glutathione/glutathione disulfide ratio between Hbbth3/+ mice treated with vehicle or mitapivat (n = 5–9 for each). Boxes represent 25th to 75th percentiles; continuous and dashed lines mark median and mean values, respectively. Whiskers indicate 90th and 10th percentiles. *P < 0.05 by 2-tailed t test. (G) Survival of CFSE-labeled red cells from WT (n = 4) and Hbbth3/+ mice treated with vehicle or mitapivat (n = 3 each group). Data are mean ± SD. (B, C, and G) *P < 0.05 compared with WT and *P < 0.05 compared with vehicle by 1-way ANOVA with Dunnett’s longitudinal comparison test. (D and E) *P < 0.02 compared with WT and *P < 0.05 compared with vehicle-treated mice.
indirect bilirubin, and lactate dehydrogenase, known markers of hemolysis, were reduced following 21 days of mitapivat treatment (Supplemental Figure 3, A and B). The survival of red cells from mitapivat-treated Hbb<sup>th3/+</sup> mice was significantly improved, with an estimated half-life of 14 ± 0.4 days, compared with 9.6 ± 0.9 days in vehicle-treated Hbb<sup>th3/+</sup> animals (P < 0.05) and 18.9 ± 0.5 days in WT controls (Figure 1G and Supplemental Table 2). No change in either creatinine or blood urea nitrogen was observed in mitapivat-treated Hbb<sup>th3/+</sup> mice when compared with vehicle-treated animals (Supplemental Figure 3C).

WT mice treated with mitapivat showed a slight but significant increase in Hb (P < 0.05) as well as an increase in MCV, MCH, and reticulocyte counts at 7 days of treatment, which generally returned toward baseline values at 14 and 21 days of treatment (Figure 1, B and C). These data suggest either a transient erythroid stimulation by mitapivat at day 7 of treatment, returning to baseline at day 21 in mitapivat-treated WT animals, or an increase in efficiency of erythropoiesis during development of late-stage precursors into reticulocytes.

Together, our findings in Hbb<sup>th3/+</sup> mice suggest that oral administration of mitapivat reduces hemolysis, improves red cell survival, and increases Hb levels.

A reduction in plasma erythropoietin (EPO) was observed in Hbb<sup>th3/+</sup> mice treated with mitapivat (Figure 2A). β-thalassemia is characterized by ineffective erythropoiesis with impaired erythroid maturation, leading to an expansion of immature erythroblast populations. In Hbb<sup>th3/+</sup> mice, mitapivat markedly decreased extramedullary erythropoiesis as supported by a reduction in the spleen/body weight ratio, decreased spleen iron content, and a reduction in spleen erythropoietic activity (Figure 2, B and C and Supplemental Figure 4A). Moreover, 3 weeks of mitapivat treatment in Hbb<sup>th3/+</sup> mice resulted in an improvement of bone marrow erythroblast maturation index, assessed as the ratio between early (pro–plus basophilic) and late (polychromatophilic plus orthochromatophilic) erythroblasts (Figure 2D). This was associated with upregulation of Cish and Serpin-3, genes strictly dependent on Stat5 function, supporting an increase in plasma EPO responsiveness in mitapivat-treated Hbb<sup>th3/+</sup> mice (Supplemental Figure 4B).

A marked increase in pyruvate kinase activity was observed in polychromatophilic and orthochromatophilic erythroblasts from mitapivat-treated Hbb<sup>th3/+</sup> mice (Supplemental Figure 4C). This was associated with a significant increase in ATP in sorted erythroid cells from spleen of mitapivat-treated Hbb<sup>th3/+</sup> mice when compared with vehicle-treated animals (P < 0.05; Figure 2E). Mitapivat administration also resulted in a marked decrease in ROS in maturing Hbb<sup>th3/+</sup> erythroblasts (Figure 2F). Apoptotic (annexin-V<sup>+</sup>) erythroblasts were significantly reduced in both spleen and bone marrow of mitapivat-treated Hbb<sup>th3/+</sup> mice (P < 0.05 for both; Figure 2G). The mitapivat-induced amelioration of ineffective erythropoiesis was accompanied by decreased Erfe (an erythroid regulator of hepcidin) expression in sorted erythroblasts as well as reduced erythroferrone (ERFE) plasma values (Figure 2, H and I). These data suggest that pyruvate kinase activation by mitapivat ameliorates the ineffective erythropoiesis observed in Hbb<sup>th3/+</sup> mice, improving EPO responsiveness and reducing oxidative stress.

**Mitapivat improved mitochondrial dysfunction in Hbb<sup>th3/+</sup> mouse erythroblasts.** Previous studies have suggested that mitochondrial dysfunction is an important feature of ineffective erythropoiesis in β-thalassemia (12, 35). Using MitoTracker, we observed that Hbb<sup>th3/+</sup> erythroblasts from mitapivat-treated mice exhibited increased clearance of mitochondria during maturation compared with vehicle-treated animals (Figure 3A). We then evaluated mRNA expression of genes involved in mitochondrial biogenesis and in quality control of inner mitochondrial membrane proteins, including (a) Atp6, Mcol, and Cyth; (b) Pgc1a, a master regulator of mitochondrial biogenesis; and (c) Ymeli, an oxidation-sensitive protease with mitochondrial-specific chaperone-like function, which provides a mechanism to sequester damaged mitochondria away from a healthy mitochondrial pool (36, 37).

In erythroblasts from mitapivat-treated Hbb<sup>th3/+</sup> mice, we observed upregulation of Atp6, Mcol, Cyth, and Pgc1a genes (Figure 3B). Although increased expression of Atp6, Mcol, and Cyth might result from a reduction in cell oxidation, the upregulation of Pgc1a indicates a specific improvement of mitochondrial function with mitapivat treatment. This was accompanied by the down-regulation of Ymeli, a mitochondria-specific chaperone, suggesting a beneficial effect of mitapivat on mitochondrial biogenesis (Figure 3C). In erythroblasts from WT mice, we observed upregulation of Atp6, Mcol, and Cyth genes, whereas no major change was observed in Pgc1a gene expression (Supplemental Figure 4D). Data from Hbb<sup>th3/+</sup> mice indicate that mitapivat treatment ameliorates mitochondrial biogenesis and improves erythropoietic mitochondrial dynamics in β-thalassemia.

**Mitapivat reduced liver iron overload and oxidative stress, and increased liver hepcidin expression in Hbb<sup>th3/+</sup> mice.** Liver iron overload is a common and severe pathological feature of β-thalassemia, a consequence of ineffective erythropoiesis and inappropriate hepcidin (Hamp) downregulation (38–40). In Hbb<sup>th3/+</sup> mice, mitapivat significantly reduced liver iron overload in both hepatocytes and Kupffer cells compared with vehicle-treated animals (P < 0.05 for both; Figure 4A). Consistently, there was a significant reduction in liver non–heme iron content in mitapivat-treated Hbb<sup>th3/+</sup> mice compared with vehicle treated Hbb<sup>th3/+</sup> mice (P < 0.05; Supplemental Figure 5A). A significant reduction in liver protein oxidation, presumably linked to a reduction in iron content, was also observed (P < 0.05; Figure 4B). As expected, on the basis of erythropoiesis improvement, mitapivat treatment resulted in upregulation of liver Hamp expression in Hbb<sup>th3/+</sup> mice (Figure 4C). This was associated with upregulation of Idi, which is linked to the activation of the SMAD system (Figure 4D). In mitapivat-treated Hbb<sup>th3/+</sup> mice, we observed decreased activation of NRF2, STAT3, and NF-kB p65 (Figure 4E), with no major change in ERK1/2 activation (Supplemental Figure 5B). These data indicate a beneficial effect of mitapivat on Hamp expression, most likely via feedback registering mitapivat-induced improvements in erythropoiesis.

**Mitapivat treatment reduced iron overload and Dmt1 expression in duodenums of Hbb<sup>th3/+</sup> mice.** Previous studies have shown that hepcidin targets ferroportin (FPN1) in the duodenum, promoting its internalization and degradation, thus modulating iron absorption (17, 41–43). Consistent with this, we observed a decrease in FPN1 staining in the duodenums of mitapivat-treated Hbb<sup>th3/+</sup> mice, with only some basolateral membrane localization left (Supplemental Figure 6A). Besides FPN1 downregulation, we observed a significant reduction of iron overload in duodenal enterocytes
Figure 2. Mitapivat ameliorated ineffective erythropoiesis in Hbb<sup>th3+</sup> mice. (A) Plasma EPO in WT and Hbb<sup>th3+</sup> mice. Data are mean ± SD (n = 3). (B) Spleen weight/mouse weight ratio in WT and Hbb<sup>th3+</sup> mice. Mean ± SD (n = 6). compared with age-matched, vehicle-treated Hbb\textsuperscript{th3/+} mice ($P < 0.05$). No overload was present in duodenums of WT mice (Figure 5A). We hypothesized that mitapivat, by increasing pyruvate kinase activity, might improve the duodenal oxidative/hypoxic intracellular environment and consequently contribute to a reduction of iron uptake by downregulation of Dmt1 expression. Indeed, mitapivat treatment also resulted in increased expression of PKR and reduced expression of stress-associated PKM2 in duodenums from Hbb\textsuperscript{th3/+} mice compared with vehicle-treated animals, suggesting a possible contribution of pyruvate kinase to small intestine metabolic function (Figure 5B, see also Supplemental Figure 6C and ref. 20). Notably, duodenum PKM2 expression was significantly higher in vehicle-treated Hbb\textsuperscript{th3/+} mice than in WT animals ($P < 0.05$), further suggesting that stress/hypoxic-response pathways are activated in duodenal cells of animals with $\beta$-thalassemia (Figure 5B and Supplemental Figure 6B). In addition, PKM2 was present as dimer in duodenum from Hbb\textsuperscript{th3/+} mice, supporting the activation of the PKM2-HIF axis (44).

As expected, in enterocytes from mitapivat-treated Hbb\textsuperscript{th3/+} mice, we observed a reduction of HIF2$\alpha$ and of the NF-$\kappa$B p65 active form (Figure 5C) as well as of both Dmt1-iron response element (IRE) and Dmt1-non-IRE mRNA transcripts (Figure 5D and 6C).
Supplemental Figure 7). In agreement, we found up- and down-regulation of PKM2-HIF targets beside Dmt1 such as Ldha, Pdk1, and Slc2a1 expression (Supplemental Figure 7) (45).

Our data suggest a novel contribution of PKM2 to iron homeostasis of Hbb<sup>th3/+</sup> mice. Mitapivat promotes the activation of pyruvate kinase and downregulation of the stress response–associated expression of PKM2. This in turn reduces activation of redox/hypoxia-related transcription factors such as the NF-κB/HIF system with downregulation of Dmt1 gene expression, which directly impacts iron absorption, resulting in a substantial clear-
In this in vitro system, mitapivat induced a slight increase in cell numbers in the late phase of erythropoiesis compared with vehicle-treated cells (Supplemental Figure 8A). This was associated with a substantial increase of orthochromatic erythroblasts at 11 and 14 days of cell culture compared with vehicle-treated β-thalassemic cells (Supplemental Figure 8, B and C). Improved β-thalassemia erythroid maturation was also supported by a significant decrease in annexin V+ cells at 11 (pro- and intermediate erythroblasts) and 14 days of cell culture (pro-, intermediate, and late erythroblasts) 

Mitapivat enhanced in vitro human erythropoiesis. We evaluated the effect of mitapivat on human erythropoiesis in an in vitro culture system based on CD34+ cells derived from peripheral blood of healthy controls and patients with β-thalassemia intermedia (46–48). This culture system recapitulates the ineffective erythropoiesis observed in vivo in β-thalassemia, exhibiting increased apoptosis and disturbed maturation.

Figure 5. Mitapivat-treated Hbbαδβ mice showed reduced ferroportin, reduced duodenum iron overload, and downregulation of the HIF2α–Dmt1 signaling axis. (A) Iron staining (Perl’s Prussian blue) in duodenums from WT and Hbbαδβ mice treated with vehicle or mitapivat. Original magnification x400. Scale bars: 100 μM. (C, right panel) Densitometric analyses of the Western blots, mean ± SD (n = 6). *P < 0.05 compared with WT or #P < 0.05 compared with vehicle-treated Hbbαδβ mice by 1-way ANOVA with Bonferroni multiple comparison correction. (D) mRNA expression of Dmt1-IRE by qRT-PCR on duodenums from WT and Hbbαδβ mice treated with vehicle or mitapivat. Experiments were performed in triplicate. Data are mean ± SD. *P < 0.05 compared with WT mice and #P < 0.05 compared with vehicle-treated mice by 2-way ANOVA with Tukey’s multiple comparisons test.
The fraction of soluble Hb in red cells from mitapivat-treated Hbbth3/+ mice compared with vehicle-treated animals. This was associated with a reduction in markers of hemolysis and a significant decrease in reticulocyte count (P < 0.05). Collectively, these data indicate that mitapivat improves quality control processes during β-thalassemic erythropoiesis. Indeed, mitapivat treatment of Hbbth3/+ mice produced a reduction in circulating erythroblasts, a marked decrease in extramedullary erythropoiesis, and an improved erythroid maturation index. In both erythropoietic sites (bone marrow and spleen), erythroblast ROS content and apoptosis markers decreased with mitapivat treatment. This was associated with increased ATP in splenic erythroblasts, with a positive trend also in bone marrow erythroblasts from mitapivat-treated Hbbth3/+ mice. Of note, mitapivat appeared to beneficially affect mitochondrial dynamics during erythropoiesis in β-thalassemia. We observed an upregulation of specific mitochondrial genes such as Pgc1a, which are known to counteract mitochondrial dysregulation and stimulate mitochondrial biogenesis in erythroblasts (52–54). We also observed downregulation of the expression of Yme1l, a mitochondrial-specific chaperone involved in mitochondrial protein quality control processes (36, 37). Taken together, these data indicated that antioxidant compounds may limit ROS cytotoxicity in β-thalassemia (1–3, 5). Indeed, mitapivat appeared to improve metabolic plasticity during erythroid maturation in Hbbth3/+ mice by ensuring cell survival and supporting cell growth.

**Discussion**

Metabolic homeostasis is extremely important in a highly dynamic cellular maturation process such as erythropoiesis (49). In β-thalassemic mouse erythroid cells, we found increased expression of PKM2, which may be part of the compensatory changes induced by the severe oxidative stress (50, 51). We reasoned that the pyruvate kinase activator mitapivat may provide additional metabolic resources in terms of more efficient glycolysis, ameliorating β-thalassemic ineffective erythropoiesis. Mitapivat treatment ameliorated anemia in Hbbth3/+ mice, increased Hb, and enhanced both red cell survival and ineffective erythropoiesis. An improved morphologic appearance of erythrocytes was accompanied by increased MCV and MCH, linked to the reduction in α-globin membrane precipitates and an increase in the fraction of soluble Hb in red cells from mitapivat-treated Hbbth3/+ mice compared with vehicle-treated animals. This was associated with a reduction in markers of hemolysis and a significant decrease in reticulocyte count (P < 0.05). Collectively, these data indicate that mitapivat improves quality control processes during β-thalassemic erythropoiesis. Indeed, mitapivat treatment of Hbbth3/+ mice produced a reduction in circulating erythroblasts, a marked decrease in extramedullary erythropoiesis, and an improved erythroid maturation index. In both erythropoietic sites (bone marrow and spleen), erythroblast ROS content and apoptosis markers decreased with mitapivat treatment. This was associated with increased ATP in splenic erythroblasts, with a positive trend also in bone marrow erythroblasts from mitapivat-treated Hbbth3/+ mice.

Of note, mitapivat appeared to beneficially affect mitochondrial dynamics during erythropoiesis in β-thalassemia. We observed an upregulation of specific mitochondrial genes such as Pgc1a, which are known to counteract mitochondrial dysregulation and stimulate mitochondrial biogenesis in erythroblasts (52–54). We also observed downregulation of the expression of Yme1l, a mitochondrial-specific chaperone involved in mitochondrial protein quality control processes (36, 37). Taken together, these data indicated that antioxidant compounds may limit ROS cytotoxicity in β-thalassemia (1–3, 5). Indeed, mitapivat appeared to improve metabolic plasticity during erythroid maturation in Hbbth3/+ mice by ensuring cell survival and supporting cell growth.
The improved erythropoiesis in mitapivat-treated Hbb\textsuperscript{th3/+} mice is accompanied by substantial changes in iron homeostasis. Perhaps as a consequence of increased responsiveness to EPO and improvements in \(\beta\)-thalassemia-associated ineffective erythropoiesis, mitapivat treatment resulted in reduced ERFE levels and upregulated \textit{Hamp} gene expression in the liver. Since we observed upregulation of \(Id1\), we hypothesize that increased \textit{Hamp} is a consequence of ameliorated ineffective erythropoiesis rather than changes in liver iron content. Consistently, duodened enterocytes from mitapivat-treated Hbb\textsuperscript{th3/+} mice exhibited decreased FPN1 content. Interestingly, mitapivat treatment induced a significant reduction in iron duodenum content (\(P < 0.05\)), combined with decreased expression of PKM2. PKM2 has been shown to translocate into the nucleus as a coactivator of transcription factors such as NF-\(\kappa\)B p65 or HIFs (14, 45, 51, 55–57). In duodenum from mitapivat-treated Hbb\textsuperscript{th3/+} mice, we observed a reduction of both HIF2\(\alpha\) expression and activation of NF-\(\kappa\)B p65. These changes were associated with downregulation of \(Dmt1\) expression in duodenum. These data indicate multiple potential targets of pyruvate kinase activation. Mitapivat treatment affects (a) iron absorption through the reduction of both NF-\(\kappa\)B p65 and HIF2\(\alpha\) function (58–61), and associated decreased \(Dmt1\) expression; and (b) iron release, by reducing FPN1 protein via hepcidin. Mitapivat should be further investigated as a \(Dmt1\) blocker to control iron absorption in disorders other than \(\beta\)-thalassemia, such as hemochromatosis (58–60). In addition, as a target of HIF2\(\alpha\), downregulation of \(Dmt1\) and subsequent improvement of anemia may occur via the hepcidin-HIF2\(\alpha\) axis, separately to the involvement of PKM2 (61). Greater clarity surrounding these complex, overlapping mechanisms could be achieved by evaluating the direct effect of mitapivat treatment on PKM2 in WT mice.

In conclusion, we show that the pyruvate kinase activator mitapivat ameliorates \(\beta\)-thalassemic ineffective erythropoiesis and improves anemia, hemolysis, and red cell survival in Hbb\textsuperscript{th3/+} mice. Mitapivat improves \(\beta\)-thalassemic pathologic erythropoiesis and modulates the ERFE-\textit{Hamp} axis, with reduction of liver iron overload. In the duodenum, mitapivat reduces the expression of PKM2, redirecting cells toward a nonhypoxic metabolic condition with reduced HIF2\(\alpha\) expression and NF-\(\kappa\)B p65 activation, both targeting \(Dmt1\) gene expression. Thus, mitapivat treatment positively affects both \(\beta\)-thalassemic ineffective erythropoiesis and iron homeostasis (Figure 6). It is worth noting that improvement of ineffective erythropoiesis and reduction of spleen erythropoiesis were reported following treatment with either the activin ligand trap RAP-011 or the glycine transporter inhibitor bitopertin (62). Mitapivat ameliorates \(\beta\)-thalassemia mouse model used here.

Our \textit{in vitro} data with CD34\textsuperscript{+} erythroid precursors from patients with \(\beta\)-thalassemia show a similar reduction in ineffective erythropoiesis markers to those observed in the Hbb\textsuperscript{th3/+} mouse model, further supporting the applicability of our experimental mouse data to the human disease. Interim results of a phase 2 clinical study with orally administered mitapivat (NCT03692052) have recently established proof of concept that pyruvate kinase activation by mitapivat has potential clinical benefit in patients with non-transfusion-dependent thalassemia (29), further confirming the relevance of the present mouse studies.

**Methods**

**Mouse strains and study design.** Two-month-old female WT C57B6 and Hbb\textsuperscript{th3/+} mice were studied (30). Blood was collected by retro-orbital venipuncture in anesthetized mice using heparinized micropipacillary tubes. Hematological parameters, red cell indices, and reticulocyte count were evaluated at baseline and at different time points, as previously reported, on a Siemens ADVIA 2120 Hematology Analyzer. Hematocrit and Hb were manually determined (31, 48, 63, 64), and o-globin membrane aggregates and soluble Hb were assayed as described by Dussiet \textit{et al.} (62). The amount of hemichromes bound to the red cell membrane was assessed as previously reported (31, 65). Total bilirubin, indirect bilirubin, lactate dehydrogenase, blood urea nitrogen (BUN), and creatinine were evaluated using standard biochemical assays, as previously reported (5, 17, 42).

To measure survival, red cells from WT or Hbb\textsuperscript{th3/+} mice treated with vehicle or mitapivat were labeled with CFSE (10 \(\mu\)M; Molecular Probes, Invitrogen) in PBS, 0.5% BSA for 20 minutes at 37°C, as previously reported (30).

Analysis of reduced GSH and of GSSG in red cells was performed according to the spectrophotometric glutathione reductase recycling procedure previously reported (66, 67), with some modifications.

The concentration of mouse EPO in plasma was determined using the Mouse Erythropoietin Quantikine ELISA Kit (R&D Systems) following the manufacturer instructions. Soluble serum ERFE was determined by ELISA, as detailed in the Supplemental Methods.

Erythrocyte morphology was assessed using May–Grünewald–Giemsa–stained smears that were imaged under oil at \(\times 100\) magnification using a PanFluor objective with 1.30 numeric aperture on a Nikon Eclipse DS-5M camera and processed with Nikon Digital Slide (DS-Li).

**Measurement of pyruvate kinase activity and ATP.** ATP concentration was determined using liquid chromatography tandem mass spectrometry (LC-MS/MS). A 4-\(\mu\)L aliquot of whole blood was mixed with 96 \(\mu\)L Milli-Q water. A 10-\(\mu\)L aliquot of the diluted blood was then mixed with 10 \(\mu\)L H\textsubscript{2}O and 200 \(\mu\)L acetonitrile/H\textsubscript{2}O (90:10, vol/vol + 0.1% NH\textsubscript{4}OH) containing the internal standards \(\text{C}_{2}H_{2}S_{2}-\text{dihydroxyphosphoglycerate} (5 \mu\text{g/mL})\) and \(\text{C}_{3}H_{25}S_{3}-\text{ATP} (2.5 \mu\text{g/mL})\). The mixture was vortexed at 1500 rpm for 2 minutes and centrifuged at 5228 \(g\) for 5 minutes. A 7.5-\(\mu\)L aliquot of supernatant was injected for analysis by LC-MS/MS. A reversed-phase gradient method was used to provide sample stacking and separation. Calibration curves were established using ATP standards. The peak area ratios of the analyte relative to the internal standard were used for quantitation.

Pyruvate kinase activity measurements were performed as described (28), except 50 \(\mu\)M of phosphoenolpyruvate was used.

**Flow cytometric analysis of mouse erythroid precursors and molecular analysis of sorted erythroid cells.** Flow cytometric analysis of erythroid precursors from bone marrow and spleen from WT and Hbb\textsuperscript{th3/+} mice was carried out using the CD44-Ter119 schema (17, 68, 69). This strategy allows identification of 4 different erythroblast subpopulations: population I, II, III, and IV, respectively corresponding to proerythroblasts, basophilic, polychromatic, and orthochromatic erythroblasts. Analysis of apoptotic orthochromatic erythroblasts was carried out on the CD44-Ter119 gated cells using the Annexin-V PE Apoptosis detection kit (eBioscience) following the manufacturer’s instructions. Erythroblast ROS levels were evaluated as previously reported using the general oxidative stress indicator, CM-H2DCFDA (10 \(\mu\)M, Thermo Fisher Scientific) on CD44-Ter119 gated populations (17). Flow
cytometric analysis of the mitochondria was carried out using the MitoTracker Deep Red probe (Thermo Fisher Scientific), following the manufacturer instructions. Details of the cytometric analysis and subsequent Western blot, quantitative real-time PCR (qRT-PCR), and mitochondrial analyses are given in the Supplemental Methods.

**Molecular analysis of liver and C-duodenum.** Protocols used for RNA isolation, cDNA preparation, and qRT-PCR have been previously described (30, 48, 62). qRT-PCR was performed using the SYBR-green method as detailed in the Supplemental Methods, with all primer sequences shown in Supplemental Table 3. Western blots were performed as described in the Supplemental Methods.

Immediately following dissection, the liver was formalin-fixed and paraffin-embedded for Perl’s staining (17). Details of quantification of spleen and liver iron content and the ferroportin (Fpn1) immunohistochemistry assay are given in the Supplemental Methods.

**In vitro human erythropoiesis.** We analyzed 10 erythroid cultures obtained from the peripheral blood of different healthy subjects and 10 erythroid cultures obtained from 4 homozygous β-thalassemia intermedia patients (β-thal E/B) who were referred to our center (48). The erythroid cell antigen profiling, the sorting of erythroid precursors, and cell culture were carried out as previously described (48) and as detailed in the Supplemental Methods. We then carried out preliminary studies of various concentrations, timings, and frequencies of addition of mitapivat for in vitro human β-thalassemia erythropoiesis testing. Since the number of CD54+ cells derivable from peripheral blood of β-thalassemia intermedia patients was too low, the dose-response experiments were carried out only in cells from healthy subjects. The preliminary experiments resulted in a protocol adding mitapivat at days 5, 7, 10, and 13 of the cell cultures.

**Statistics.** Data were analyzed using either t test or 1-way ANOVA (Dunnett’s test) for longitudinal studies or 2-way ANOVA with Bonferroni connection for repeated measures between the mice of various genotypes, as well as between healthy and β-thalassemic cells. A difference with a P less than 0.05 was considered significant.

**Study approval.** The Institutional Animal Experimental Committee of the University of Verona (CIRSAL) and the Italian Ministry of Health approved the experimental protocols (56DC9.12), following European directives 2010/63/EU and the Federation for Laboratory Animal Science Associations guidelines and recommendations. The study was approved by the Ethical Committee of the Azienda Ospedaliera Integrata Verona, Italy (FCRF131FT). Written informed consent was obtained from patients with β-thalassemia and healthy controls.

**Author contributions**

GF, FC, MAD, LS, CL, MTV, AJ, AI, CB, and LDF wrote the manuscript. AM, CB, and LDF designed the experiments. SY and SR carried out 2,3-DPG and ATP determinations. AM carried out standard hematology, cyt fluorometric analysis, ELISA, and Western blot experiments. EF and II carried out immunoblot experiments. PAK carried out pyruvate kinase activity experiments and contributed to manuscript revision. RN carried out ATP experiments. CK and LD contributed to therapeutic concept and manuscript revision. TG and CLJ carried out soluble ERFE measurements and contributed to manuscript revision. RR and AI carried out RT-PCR analyses. GF and FC carried out Fpn1 studies. MAD and LS carried out mitochondria studies. FT carried out the analyses of hemichromes. AJ and CL carried out blinded pathologic analyses. EB carried out CD34-derived liquid cultures. AM, EF, CK, PAK, GF, FC, MAD, LS, MTV, FT, EB, II, LD, TG, CLJ, AI, CB, and LDF analyzed data.
