Harlequin ichthyosis (HI) — the most severe form of keratinizing disorders, often lethal in the neonatal period — is characterized by a profound thickening of the keratin skin layer, a dense “armor”-like scale that covers the body, and contraction abnormalities of the eyes, ears, and mouth. In this issue of the *JCI*, Akiyama et al. report that mutations in *ABCA12* caused defective lipid transport that significantly impacted normal development of the skin barrier. Lipid secretion was recovered after corrective *ABCA12* gene transfer into patient keratinocytes. These results should allow for early prenatal diagnosis of HI and lend hope to the possibility of a specific treatment for this devastating disorder.
renal stem cells (Figure 1). The failure of whole bone marrow to have this protective effect (12) may be due to the extremely small numbers of MSCs present in the bone marrow or the large numbers of inflammatory cells infused in this preparation. It remains unclear whether the protective effect of MSCs requires them to leave the bone marrow and transit through the renal circulation or whether these cells can exert protective effects from distant sites. Identifying the protective factor(s) and the signals that prompt MSCs to secrete it should now be a priority in our attempts to develop new therapeutic approaches for improving patient outcomes following acute renal failure.

Harlequin ichthyosis unmasked: a defect of lipid transport

Alain Hovnanian

Department of Medical Genetics and INSERM U563, Purpan Hospital, Toulouse, France.

Harlequin ichthyosis (HI) — the most severe form of keratinizing disorders, often lethal in the neonatal period — is characterized by a profound thickening of the keratin skin layer, a dense “armor”-like scale that covers the body, and contraction abnormalities of the eyes, ears, and mouth. In this issue of the JCI, Akiyama et al. report that mutations in ABCA12 caused defective lipid transport that significantly impacted normal development of the skin barrier (see the related article beginning on page 1777). Lipid secretion was recovered after corrective ABCA12 gene transfer into patient keratinocytes. These results should allow for early prenatal diagnosis of HI and lend hope to the possibility of a specific treatment for this devastating disorder.

Waring pointed to what is believed to be the first harlequin fetus described in the US in the diary of Reverend Oliver Hart in 1750 (1). Harlequin ichthyosis (HI) is believed to be inherited in an autosomal-recessive manner, and affected newborn infants are encased in “armor”-like thick, yellow plates of scales with deep red fissuring. The skin is pulled tight such that the face loses its normal appearance and the body is pulled taut. The skin is pulled tight such that the face loses its normal appearance and the body is pulled taut. Liveborn infants usually die within the first days of life from respiratory, infectious, and/or dehydration-related complications. Some patients treated with retinoids, synthetic derivatives of vitamin A, have survived and subsequently develop severe ichthyosis. The cause of HI, however, has remained elusive, and late prenatal diagnosis has until now relied on electron microscopic examination of tissue sampled by invasive fetal skin biopsy.

Lipid transport: a likely suspect

Members of the ABCA subclass of the large ABC transporter protein family bind ATP for the active transport of lipids across cell membranes against a concentration gradient. ABCA1 has been shown to be the causative gene in Tangier disease, a disorder of cholesterol transport between liver and other tissues (2–5), while mutations in ABCA4 (expressed exclusively in photoreceptors of the eye for the transport of retinol) cause Stargardt disease, recessive retinitis pigmentosa, or cone-rod dystrophy, in which the abnormal accumulation of retinoids results in the development of macular dystrophy and loss of central vision (6–8).

Lipid processing in the skin is essential for the protective function of the stratum corneum, the most external layer of the epidermis (9). Corneocytes, attached to each other by corneodesmosomes and embedded in intercellular lipid lamellae, form a cornified layer that acts as a barrier between the internal and external environment for bodily defense. The lipid lamellae are derived from lamellar granules, the

Nonstandard abbreviations used: HI, harlequin ichthyosis.

Lipid transport: a likely suspect

Members of the ABCA subclass of the large ABC transporter protein family bind ATP for the active transport of lipids across cell membranes against a concentration gradient. ABCA1 has been shown to be the causative gene in Tangier disease, a disorder of cholesterol transport between liver and other tissues (2–5), while mutations in ABCA4 (expressed exclusively in photoreceptors of the eye for the transport of retinol) cause Stargardt disease, recessive retinitis pigmentosa, or cone-rod dystrophy, in which the abnormal accumulation of retinoids results in the development of macular dystrophy and loss of central vision (6–8).

Lipid processing in the skin is essential for the protective function of the stratum corneum, the most external layer of the epidermis (9). Corneocytes, attached to each other by corneodesmosomes and embedded in intercellular lipid lamellae, form a cornified layer that acts as a barrier between the internal and external environment for bodily defense. The lipid lamellae are derived from lamellar granules, the
major lipid-rich organelles present in epidermal granular cells, which originate from the trans-Golgi network. Lamellar granules contain polar lipids (cholesterol sulfate, phospholipids, sphingomyelin, and glucosylceramides) that are the precursors of the intercellular lipids of the stratum corneum. Along with lipids, lamellar granules also transport lipid-processing enzymes and proteases and their inhibitors, all of which play a role in barrier permeability and the control of the desquamation process (10). Lipid-processing enzymes include acid hydrolases, acid sphingomyelinase, β-glucocerebrosidase, and secretory phospholipase A2. At the interface between the granular layer and the first layer of the stratum corneum, lamellar granules normally fuse with the apical cell surface and discharge their lipid contents into the intercellular space; this results in complex changes in lipid composition via the action of these enzymes to form lipid lamellae of the stratum corneum (Figure 1A). The lipid lamellae contain equimolar mixtures of ceramides, cholesterol, and free fatty acids. These structures provide very effective protection against external aggressions and fluid loss.

In a previous study, electron microscopy in HI patients revealed that lamellar granules are either absent or abnormal and that no intercellular lamellae are present (11) (Figure 1B). These data suggest that this defect in the lamellar granules results in thickening of the stratum corneum and the accumulation of armor-like scales in HI. However, the genetic basis for these events had not been elucidated.

Figure 1
Mutations in lipid transporter ABCA12 cause HI. (A) In the granular layers of healthy skin, the ABCA12 lipid transporter transfers lipids from the cytosol into lamellar granules where lipid-processing enzymes, proteases, and protease inhibitors are also concentrated. At the granular layer–stratum corneum interface, the lamellar granules fuse with the cell membrane and discharge their content into the intercellular lamellae. Complex enzymatic reactions lead to modifications of the lipid composition of the intercellular space (cholesterol, ceramides, free fatty acids) that provide a very effective water-permeability barrier. Corneocytes detach from each other in the superficial layers of the stratum corneum as a result of finely regulated proteolytic cleavage of corneodesmosomes. (B) In the skin of HI patients, the absence of ABCA12 prevents the transfer of lipids into lamellar granules, which themselves are abnormally shaped, reduced in number, or absent. As a result, exocytosis of lamellar granule content is reduced and intercellular lipid lamellae are absent. Abnormal lipid-containing vacuoles form in the cytoplasm of the corneocytes. The stratum corneum is remarkably thickened and does not desquame.
Defects in lipid-processing enzymes have previously been shown to cause several other forms of ichthyosis. These include defects in: (a) the steroid sulfatase in X-linked recessive ichthyosis (12); (b) β-glucocerebrosidase in Gaucher disease (13); (c) sphingomyelinase in Niemann-Pick disease (14); (d) fatty acid dehydrogenase in Sjögren-Larsson syndrome (15); (e) lipoxigenase-3 and 12R-lipoxygenase in autosomal-recessive congenital ichthyosis (16); and (f) CGI-58 in Chanarin-Dorfman syndrome (17). Although none of these ichthyoses are as severe as HI, they illustrate that a major role for lipid abnormalities exists in the pathophysiology of ichthyosis.

Mutations in ABCA12 revealed

In this issue of the JCI, Akiyama et al. (18) demonstrate that HI is caused by loss-of-function mutations in ABCA12, which codes for a lamellar granule membrane protein involved in lipid transport (Figure 1A). Together with the knowledge that mutations in ABCA1 and ABCA4 cause Tangier disease and Stargardt disease, respectively, this most recent discovery further supports a pivotal role for ABCA class lipid transporters, ABCA3 and ABCA12, which are essential for the production of alveolar surfactant and lipid lamellae in the stratum corneum, respectively. At birth, while ABCA3 prevents the lungs from collapsing, ABCA12 protects the skin from external aggressions and water loss. Loss of ABCA12 expression results in the most severe dysregulation of cornification in humans, covering the newborn infant in a lethal type of armor. Not only will these findings dramatically improve our ability to offer mutational screening and early DNA-based prenatal diagnosis of HI, but they will also allow for the development of new and specific therapeutic approaches.

Implications for therapy and prenatal diagnosis

Akiyama et al. (18) also showed that genetic correction of ABCA12 deficiency by gene transfer in patients’ keratinocytes restored normal glucosylceramide cell distribution and lamellar granule formation. This result raises the possibility of HI treatment using systemic administration of functional peptides with ABCA12-like properties or ABCA12 gene delivery approaches undertaken either prior to or after birth. This discovery of the role of ABCA12 in HI reveals a major role of lipid transport in the formation of the skin barrier and its function. This is a very elegant illustration of adaptive evolution to terrestrial life, involving 2 closely related lipid transporters, ABCA3 and ABCA12, which are essential for the production of alveolar surfactant and lipid lamellae in the stratum corneum, respectively. At birth, while ABCA3 prevents the lungs from collapsing, ABCA12 protects the skin from external aggressions and water loss. Loss of ABCA12 expression results in the most severe dysregulation of cornification in humans, covering the newborn infant in a lethal type of armor. Not only will these findings dramatically improve our ability to offer mutational screening and early DNA-based prenatal diagnosis of HI, but they will also allow for the development of new and specific therapeutic approaches.
