The AKT/mammalian target of rapamycin (AKT/mTOR) and ERK MAPK signaling pathways have been shown to cooperate in prostate cancer progression and the transition to androgen-independent disease. We have now tested the effects of combinatorial inhibition of these pathways on prostate tumorigenicity by performing preclinical studies using a genetically engineered mouse model of prostate cancer. We report here that combination therapy using rapamycin, an inhibitor of mTOR, and PD0325901, an inhibitor of MAPK kinase 1 (MEK; the kinase directly upstream of ERK), inhibited cell growth in cultured prostate cancer cell lines and tumor growth particularly for androgen-independent prostate tumors in the mouse model. We further showed that such inhibition leads to inhibition of proliferation and upregulated expression of the apoptotic regulator Bcl-2–interacting mediator of cell death (Bim). Furthermore, analyses of human prostate cancer tissue microarrays demonstrated that AKT/mTOR and ERK MAPK signaling pathways are often coordinately deregulated during prostate cancer progression in humans. We therefore propose that combination therapy targeting AKT/mTOR and ERK MAPK signaling pathways may be an effective treatment for patients with advanced prostate cancer, in particular those with hormone-refractory disease.

The AKT/mammalian target of rapamycin (AKT/mTOR) and ERK MAPK signaling pathways have been shown to cooperate in prostate cancer progression and the transition to androgen-independent disease. We have now tested the effects of combinatorial inhibition of these pathways on prostate tumorigenesis by performing preclinical studies using a genetically engineered mouse model of prostate cancer. We report here that combination therapy using rapamycin, an inhibitor of mTOR, and PD0325901, an inhibitor of MAPK kinase 1 (MEK; the kinase directly upstream of ERK), inhibited cell growth in cultured prostate cancer cell lines and tumor growth particularly for androgen-independent prostate tumors in the mouse model. We further showed that such inhibition leads to inhibition of proliferation and upregulated expression of the apoptotic regulator Bcl-2–interacting mediator of cell death (Bim). Furthermore, analyses of human prostate cancer tissue microarrays demonstrated that AKT/mTOR and ERK MAPK signaling pathways are often coordinately deregulated during prostate cancer progression in humans. We therefore propose that combination therapy targeting AKT/mTOR and ERK MAPK signaling pathways may be an effective treatment for patients with advanced prostate cancer, in particular those with hormone-refractory disease.

Introduction

Prostate cancer is one of the most common neoplasms, particularly among aging males in the United States. Like many adenocarcinomas, prostate tumors arise from preinvasive lesions, mainly prostatic intraepithelial neoplasia (PIN), which ultimately progress to adenocarcinoma and, in some cases, metastatic disease (1). Cancer progression, as well as all aspects of normal prostate differentiation, are critically dependent upon androgen receptor (AR) signaling (2).

While the prognosis for men diagnosed with early-stage disease has improved considerably in recent years, due to advances in the treatment of organ-confined prostate cancer, there are still few effective therapeutic options for advanced prostate cancer (3–5). The most common, namely abrogation of AR signaling via hormone deprivation therapy, is initially effective but ultimately leads to hormone-refractory disease (6–8). Prostate cancer cells share many key molecular pathways that are known to be altered in prostate cancer (15, 17, 18). In particular, these mutant mice have now tested the effects of combinatorial inhibition of these pathways on prostate tumorigenesis by performing preclinical studies using a genetically engineered mouse model of prostate cancer. We report here that combination therapy using rapamycin, an inhibitor of mTOR, and PD0325901, an inhibitor of MAPK kinase 1 (MEK; the kinase directly upstream of ERK), inhibited cell growth in cultured prostate cancer cell lines and tumor growth particularly for androgen-independent prostate tumors in the mouse model. We further showed that such inhibition leads to inhibition of proliferation and upregulated expression of the apoptotic regulator Bcl-2–interacting mediator of cell death (Bim). Furthermore, analyses of human prostate cancer tissue microarrays demonstrated that AKT/mTOR and ERK MAPK signaling pathways are often coordinately deregulated during prostate cancer progression in humans. We therefore propose that combination therapy targeting AKT/mTOR and ERK MAPK signaling pathways may be an effective treatment for patients with advanced prostate cancer, in particular those with hormone-refractory disease.

Nonstandard abbreviations used: BPH, benign prostatic hyperplasia; CI, combination index; MEK, MAPK kinase 1; mTOR, mammalian target of rapamycin; S6K, p70 S6 kinase; PCA, prostate adenocarcinoma; PIN, prostatic intraepithelial neoplasia; TMA, tissue microarray.

Conflict of interest: The authors have declared that no conflict of interest exists.

human prostate cancer are also altered during cancer progression in these mice (19–21). Most relevant for the current study, Nkx3.1; Pten mutant mice display activation of AKT/mTOR and ERK MAPK signaling during prostate cancer progression in androgen-dependent and androgen-independent contexts (15). Therefore, we reasoned that these Nkx3.1; Pten mice should provide an excellent preclinical model to test the consequences of combinatorial targeting of AKT/mTOR and ERK MAPK signaling for prostate tumorigenesis.

We now report that combinatorial inhibition of the AKT/mTOR and ERK MAPK signaling pathways is highly effective for inhibition of prostate tumorigenicity in vivo, particularly for androgen-independent tumors. Furthermore, our analyses of the status of the PTEN/AKT/mTOR signaling pathway in human prostate tumors, as well as its correlation with activation of ERK MAPK signaling, confirm that these pathways are frequently deregulated in human prostate cancer and are, therefore, suitable targets for therapeutic intervention. We propose that combination therapy targeting the AKT/mTOR and ERK MAPK signaling pathways may be applicable to a broad spectrum of patients with advanced prostate cancer, particularly those with hormone-refractory disease, for which novel treatment options are urgently needed.

Results

Inhibition of AKT/mTOR and ERK MAPK signaling pathways with rapamycin and PD0325901. Based on previous studies showing that AKT/mTOR and ERK MAPK signaling pathways synergize to promote prostate tumorigenicity in human prostate cancer cell lines in culture as well as in Nkx3.1; Pten mutant mice in vivo (15, 16), we hypothesized that targeted therapy to combinatorially inhibit these signaling pathways would be effective for blocking prostate tumor growth. Therefore, we developed experimental paradigms to test the consequences of inhibiting these pathways individually or together in androgen-dependent and androgen-independent prostate tumors in the Nkx3.1; Pten mutant mice (Figure 1A).

In deciding upon the appropriate agents to test this hypothesis, our primary considerations were: (a) the accessibility/availability of relevant small-molecule inhibitors for these pathways; (b) the appropriateness of such agents for use in vivo as well as in cell culture; and (c) the feasibility of using such agents combinatorially. To achieve inhibition of ERK MAPK signaling, we opted to target MEK kinase, since it is directly upstream of ERK, which is considered to be its primary target (12). Notably, several MEK inhibitors are now available that have been shown to have potent anticaner growth properties, some of which are currently in clinical trials (22–24). For these studies, we used PD0325901 (from Pfizer), which is similar to its predecessor CI-1040 (24), albeit reported to have improved potency (22).

In lieu of AKT, effective inhibitors for which are still not widely available, we chose to target mTOR, since many of the downstream consequences of the AKT kinase are thought to be mediated through mTOR signaling (25, 26) and since components of the mTOR pathway have been shown to be activated in advanced prostate cancer (10). Moreover, unlike inhibitors of AKT, inhibitors of mTOR, namely rapamycin and its derivatives (e.g., CCI-779 from Wyeth and RAD001 from Novartis), are now readily available and considered to be promising anticancer agents (27). Notably, although their efficacy as single agents may be limited, rapamycin and related compounds are considered to be particularly suitable for use in combination therapy (e.g., refs. 27, 28). For these preclinical studies, we chose to use rapamycin (rather than one of the newer derivatives), since it is commercially available and therefore logistically more feasible to use in combination with PD0325901, which is obtained from Pfizer.

Although rapamycin and PD0325901 have been used as single agents in genetically engineered mice (24, 29–33), it was first necessary to define the optimal experimental parameters for their use in combination in vivo. To do so, we performed pilot studies in the Nkx3.1; Pten mutant mice to verify the optimal dosage as well as the appropriate dosing schedule for the agents delivered individually or in combination. For these and most subsequent studies, we used phosphorylation of S6 (p-S6), which is downstream of mTOR, as an indicator of mTOR pathway activity and phosphorylation (i.e., activation) of ERK MAPK as an indicator of MEK inhibition.

In general, we found that the optimal use of these agents in combination was similar to their previously reported use as single agents. In particular, we found that a single dose of rapamycin plus PD0325901 delivered to the Nkx3.1; Pten mutant mice individually or together resulted in the effective inhibition of their respective targets (i.e., p-S6 and p-ERK, respectively) for up to 24 hours (Figure 1B). Moreover, we found that the appropriate doses of rapamycin and PD0325901 needed to achieve effective inhibition of their respective targets, while resulting in limited toxicity or loss of body weight (see Supplemental Table 1; supplemental material available online with this article; doi:10.1172/JCI34764DS1), were similar to those in published reports for their use as single agents. In particular, we found that i.p. delivery of 10 mg/kg of rapamycin resulted in significant inhibition of p-S6, and conversely that oral delivery of 20 mg/kg of PD0325901 resulted in effective inhibition of p-ERK, as evident by immunostaining and Western blot analyses of prostate tissues (Figure 1, B–J). Therefore, for these preclinical studies, we implemented a once-daily dosing schedule using 10 mg/kg of rapamycin and/or 20 mg/kg of PD0325901.

Rapamycin and PD0325901 synergize to inhibit prostate cell growth in culture. To quantify the individual and combinatorial effects of rapamycin and PD0325901, we performed studies in culture using mouse CASP prostate cancer cell lines, which were generated from primary tumors from the Nkx3.1; Pten mutant mice and include both androgen-responsive (CASP 2.1) and androgen-independent (CASP 1.1) lines (15, 19). First, we evaluated the IC_{50} of the single agents, which was 0.3 nM for rapamycin and 40 nM for PD0325901 in these CASP cells (Figure 2, A and B). In contrast, the IC_{50} of the agents in combination was shifted to 0.0018 nM for rapamycin and 11 nM for PD0325901 (Figure 2, C and D). To determine whether the shift in IC_{50} for the combination reflected their synergism in cell culture, we assessed their combination index (CI), which, as calculated based on the Chou-Talalay equation, provides a means of quantifying the differential sensitivity of agents in combination (34). The CI takes into account both potency (IC_{50}) and the shape of the dose-effect curve, such that a CI value of less than 1 indicates synergism, a CI value of 1 indicates an additive effect, while a value greater than 1 indicates antagonism. We found that rapamycin and PD0325901 displayed extremely low CIs (i.e., in the range of 0.03–0.1; Figure 2E), indicating their strong synergism in cell culture.

To gain initial insights regarding the mechanistic basis for the combinatorial effects of rapamycin and PD0325901, we investigated the expression status of various apoptotic regulatory proteins. We found that Bim (35, 36) was upregulated in response to the drug treatment, which is notable, since it has been shown to be upregulated by inhibitors of mTOR and MEK in other cell types.
Notably, while rapamycin and PD0325901 effectively inhibited their target pathways when used individually or in combination, upregulation of Bim expression was most marked when the drugs were used in combination (Figure 2F). Furthermore, we found that siRNAi-mediated knockdown of Bim resulted in a partial rescue of the consequences for cell survival in MTT assays, suggesting that the activity of these agents is mediated at least in part by upregulation of Bim (Figure 2G).

Collectively, these data suggest that rapamycin and PD0325901 act synergistically to promote cell death in culture, which reflects, at least in part, their combinatorial effects on the apoptotic regulator Bim. Furthermore, although our study is primarily focused on the efficacy of these agents in mutant mice, we have found that these agents also inhibit their respective pathways in human prostate cancer cells (Supplemental Figure 1), which suggests that these agents may have a similar benefit in human prostate cancer.

Preclinical analyses of combination therapy with rapamycin and PD0325901. Having demonstrated the combinatorial efficacy of rapamycin and PD0325901 for inhibiting their respective target pathways in prostate cells in vivo and in culture, as well as having established optimal experimental conditions for their combined use in vivo, we next investigated their potential antitumor effects in Nkx3.1; Pten mutant mice. In particular, we performed preclinical studies to compare the consequences of these agents for: (a) treatment of androgen-dependent prostate cancer (i.e., in mice that were androgen-intact); and (b) treatment of androgen-inde-
pendent prostate cancer (i.e., in mice that had been castrated and had developed hormone-refractory tumors) (Figure 1A).

We used Nkx3.1; Pten mutant mice (i.e., Nkx3.1<sup>−/−</sup>; Pten<sup>−/−</sup> or Nkx3.1<sup>−/−</sup>; Pten<sup>+/−</sup>) or wild-type littermates (i.e., Nkx3.1<sup>+/+</sup>; Pten<sup>+/−</sup>) at 10–12 months, by which age the mutant mice display virtually complete penetrance of high-grade PIN with associated adenocarcinoma, as well as complete penetrance of hormone-refractory tumors following surgical castration (Figure 1A) (15, 17, 18). Cohort groups were composed of mutant (or control) mice randomly assigned to receive vehicle alone, single agents (rapamycin or PD0325901), or the combination therapy (rapamycin plus PD0325901) (Table 1 and Supplemental Table 1). Agents were provided for a period of 3 weeks using a dosage schedule of once daily for 5 days, with 2 days off to allow the mice to recover. Endpoint analyses included semiquantitative histological, immunohistochemical, and Western blot analyses, as well as quantitative assessments of prostate tissue weights and proliferation index (Figures 3–5; summarized in Table 1 and Supplemental Table 1); notably, we assessed outcome based on analyses of the combination of these various endpoints rather than any individual parameter.

To augment these studies in the whole animal, we performed complementary studies using a tissue recombination model in...
which prostate epithelium from Nkx3.1; Pten mutant (or wild-type) mice is combined with wild-type rat mesenchyme and grown under the kidney capsule of androgen-intact or androgen-ablated nude male hosts (15) (Figure 6 and Supplemental Table 1). This strategy complements studies done in the whole animal (i.e., in the Nkx3.1; Pten mutant mice) in 2 important respects. First, it enables evaluation of the efficacy of combination therapy in vivo for the intended target cells (i.e., the prostate epithelial cells), as opposed to the target tissue (i.e., intact prostate). Second, because of the nature of how the tissue recombinants are made, tumor growth is relatively uniform (and therefore more easily quantified) in the tissue recombinant model, in contrast to the intrinsically more heterogeneous tumor growth that occurs in the whole animal. However, since preclinical studies are inherently more meaningful in the context of the whole animal with an intact immune response, studies done in the Nkx3.1; Pten mutant mice and the tissue recombination model are complementary, not redundant.

Combination therapy with rapamycin and PD0325901 is potently antitumorigenic for androgen-independent prostate cancer. To test the efficacy of rapamycin and PD0325901 for the treatment of androgen-dependent prostate cancer, we performed preclinical studies in androgen-intact Nkx3.1; Pten mutant mice as well as in tissue recombinants grown in androgen-intact nude male hosts using the experimental conditions outlined above (Figure 3, Figure 5, A–D, Figure 6, A–H, Table 1, and Supplemental Table 1). We found that, whether delivered individually or in combination, rapamycin and PD0325901 effectively inhibited their respective target pathways in prostate tissues, as evidenced by immunohistochemistry and Western blot analysis for p-S6 and p-ERK (Figure 3, F–M, and Figure 5D). Notably, in combination, these agents resulted in a more striking inhibition of their target proteins, as well as inhibition of p-AKT (Figure 3, B–Q, and Figure 5D).

Nonetheless, both the single agents and the combination were only modestly effective for inhibiting prostate tumorigenicity in this context. For example, the combination therapy produced a modest, albeit not statistically significant, reduction in prostate weight in the whole animal (1.7-fold; \(P = 0.111\)) and proliferation rate (2.4-fold; \(P = 0.165\)) (Figure 3, R–U, Figure 5, B and C, and Table 1). However, in the tissue recombinant model, the drug combination did result in a significant inhibition of tumor size (2.6-fold; \(P = 0.033\)) (Figure 6, A–H), which likely reflects the uniformity of tumor growth in the tissue recombinants relative to the whole animal. Therefore, although rapamycin and PD0325901 effectively inhibit mTOR and ERK MAPK signaling in androgen-dependent prostate cancer, they do not optimally inhibit tumor growth in this context.

In striking contrast, rapamycin and PD0325901 were highly effective for inhibiting androgen-independent tumor growth in the Nkx3.1; Pten mutant mice (Figure 4, Figure 5, E and F, and Figure 6, I–P). In particular, both the single agents and the combination therapy resulted in inhibition of their respective target proteins, p-S6 and p-ERK, although as above, the combination produced a more profound inhibition of these proteins as well as the additional inhibition of p-AKT (Figure 4, B–Q, and Figure 5H). Moreover, while the single agents each resulted in a statistically significant reduction in tumor size and proliferation (see Table 1 and Figure 5, F and G), the combination therapy produced a profound abrogation of the histological phenotype, as well as a significant reduction in tumor weights (2.2-fold; \(P = 0.0002\)) and cellular proliferation (14.7-fold; \(P = 0.0001\)) (Figure 4, B–E and R–U, Figure 5, F and G, and Table 1). Moreover, the efficacy of this drug combination for androgen-independent prostate cancer was recapitulated in the tissue recombination model of the disease (3.2-fold; \(P = 0.007\)) (Figure 6, I–P). These findings demonstrate that combination therapy targeting the AKT/mTOR and ERK MAPK signaling pathways is highly effective for the treatment of hormone-refractory prostate cancer in a preclinical model of the disease.

Considering the profound effects of this combination therapy for inhibiting androgen-independent prostate cancer, we investigated whether this drug combination might also be effective in an adjuvant therapy model for hormone-refractory prostate cancer.

AD, androgen-dependent; AI, androgen-independent.
Specifically, rapamycin and PD0325901 were provided for a period of 3 weeks directly following androgen ablation of the Nkx3.1; Pten mutant mice or tissue recombinants grown in the nude mice (Figure 7 and Table 1). In this context, the drug combination was highly effective for inhibiting prostate tumor growth, as evidenced by the striking effects on the histological phenotype, as well as the significant reduction in the prostate weight (3.3-fold; $P = 0.012$) and cellular proliferation (3.4-fold; $P = 0.035$) in the Nkx3.1; Pten mutant mice and in the analogous tissue recombination model (2.2-fold; $P = 0.018$) (Figure 7). Therefore, this combination therapy may be promising for adjuvant therapy of hormone-refractory prostate cancer when used in combination with androgen deprivation therapy.

AKT/mTOR and ERK MAPK signaling pathways are coordinately regulated in human prostate cancer. Extrapolating from these preclinical studies in the mutant mouse model, our findings suggest that combination therapy targeting the AKT/mTOR and ERK MAPK signaling pathways may be beneficial for treatment of patients with hormone-refractory prostate cancer. Notably, the potential to translate these findings from mice to human prostate cancer is particularly promising considering that the combination is effective for inhibiting their target pathways in human prostate cancer cells (Supplemental Figure 1) and since the single agents (or related agents) are already being used in clinical trials (22, 27).

However, the efficacy and expected versatility of the combination therapy depends, in part, upon: (a) the frequency with which these signaling pathways are deregulated individually and combinatorially in human prostate cancer, particularly in patients with advanced disease; and (b) the ease of identifying patients who have primary tumors in which these pathways are deregulated and, therefore, would be appropriate candidates for targeted therapy.

While these issues have been partially addressed in previous studies that have examined the status of individual components of these signaling pathways in human prostate cancer (e.g., refs. 8–11, 13), we have now performed a comprehensive analysis in primary tumors and metastases from human prostate cancer patients to evaluate the coordinate expression of multiple components of the PTEN/AKT/mTOR signaling pathway, as well as their status relative to ERK MAPK signaling (Figure 8 and Table 2). In particular, we performed analyses using 2 independent cohorts of patients assembled on 2 independent tissue microarrays (TMAs). This com-
A comprehensive series enabled us to examine the coordinate expression of several components of the PTEN/AKT/mTOR pathway, as well as ERK MAPK, in specimens from patients with benign prostatic hyperplasia (BPH); PIN; prostate adenocarcinoma (PCa), including those with low Gleason (≤6) or high Gleason (>7) scores; hormone-refractory cancer; and metastases. In particular, we examined the expression levels of PTEN as well as the activation (phosphorylation) of AKT, mTOR, and p70 S6 kinase (S6K) relative to each other as well as to activation of ERK MAPK.

The first TMA comprised 70 samples, including 25 cases of BPH, 7 of PIN, 19 of low Gleason score cancer, and 19 of high Gleason score cancer (Table 2). We found that PTEN expression was markedly reduced with high frequency (59% cases) during prostate cancer progression, as determined by comparing BPH, PIN, and PCa (P = 0.05; Figure 8, A–C; PIN data not shown). We further found that the expression levels of both p-AKT and p-mTOR were significantly elevated in prostate cancer compared with BPH and PIN (P = 0.001; Figure 8, D–I; PIN data not shown). Similarly, p-S6K expression was significantly higher in prostate cancer compared with BPH and PIN (P < 0.0001; Figure 8, J–L; PIN data not shown).

Notably, when activated, these proteins were frequently activated in the same patient samples and also coincident with reduced expression of PTEN (Figure 8, C, F, I, L, and O, and Tables 2–4), indicating that the pathway rather than the individual components are coordinately deregulated.

To further validate these results, as well as the potential clinical implications of identifying an altered PTEN/AKT/mTOR signaling pathway in prostate cancer, we used a second TMA composed of an independent cohort of prostate cancer patients. This TMA represented a large, well-characterized group of 535 patients, including 65 cases of BPH, 78 of PIN, 181 of organ-confined cancer, 120 of hormone-refractory cancer, and 91 of metastatic PCa. We found that decreased levels of PTEN were significantly associated with disease progression, mainly when comparing primary and metastatic prostate cancer (P = 0.001). Similarly, increased levels of p-AKT (P = 0.02), p-mTOR (P = 0.02), and p-S6K (P = 0.03) were also found to be significantly associated with tumor progression. Furthermore, these proteins were often activated together and with reduced expression of PTEN, again indicative of deregulation of the signaling pathway.

Figure 4
Profound efficacy for prostate histology following treatment of androgen-independent prostate cancer with rapamycin and PD0325901. (A) Diagram of the experimental strategy, as per Figure 1. (B–U) Representative tissue sections from the androgen-ablated Nkx3.1+/− Pten+/− mutant mice treated with the single or combination of agents, showing histological phenotype (H&E) and immunostaining for the antibodies indicated. In these and all subsequent experiments, H&E analysis was performed on all experimental mice in each group; immunohistochemistry was done on a minimum of 4 animals from each group; representative data are shown. Scale bars: 100 μm.
Finally, using this first TMA, we examined the expression of ERK MAPK in human prostate tumor samples, compared with the deregulation of the PTEN/AKT/mTOR signaling pathway (Tables 2–4). Immunohistochemical analysis of p-ERK expression showed that it was focally expressed and at low levels in BPH samples and PIN lesions (Figure 8M; PIN data not shown). However, p-ERK was highly expressed in the majority of cancer samples, and increased levels of ERK MAPK were significantly associated with tumor progression in PIN and low-grade tumors versus high-grade lesions ($P = 0.008$; Figure 8, M–O). Furthermore, when compared with deregulated expression of the PTEN/AKT/mTOR signaling pathway, we found that 21% of patients with prostate cancer displayed deregulated expression of all components of the PTEN/AKT/mTOR signaling pathway as well as ERK MAPK, while 42% of these patients displayed deregulated expression of 1 or more components of the PTEN/AKT/mTOR signaling pathway as well as ERK MAPK (Table 4).

In conclusion, the PTEN/AKT/mTOR signaling pathway is frequently altered in prostate cancer progression and often coincidentally with activation of ERK MAPK signaling. These data support the concept that a substantial number of patients with advanced prostate cancer (conservatively at least 20%) may benefit from combination therapy targeting the AKT/mTOR and ERK MAPK signaling pathways. Furthermore, since the relevant activated target...
proteins can be readily detected in primary tumors from patient samples, it should be feasible to identify patients that are most likely to respond to treatment, namely those that display deregulation of PTEN/AKT/mTOR and/or ERK MAPK signaling.

Discussion
In our previous investigations of the molecular mechanisms underlying prostate cancer progression, we found that the AKT/mTOR and ERK MAPK signaling pathways function cooperatively to promote prostate tumorigenicity and androgen independence (15). Based on these findings, we had hypothesized that combinatorial inhibition of these pathways might be effective for the treatment of prostate cancer. We now demonstrate that inhibition of these signaling pathways acts combinatorially to suppress pathway activation and inhibit tumor growth and cellular proliferation in androgen-independent prostate cancer in Nkx3.1−/−; Pten−/− mutant mice. Furthermore, analyses of human prostate tumor specimens support the idea that AKT/mTOR and ERK MAPK signaling pathways are frequently activated in prostate tumors, readily detected in advanced human prostate cancer, and are suitable targets for intervention in patients with the disease. We propose that combination therapy targeting the AKT/mTOR and the ERK MAPK signaling pathways may be effective for treatment of a broad spectrum of patients with advanced prostate cancer, particularly those with hormone-refractory disease.

Figure 6
Combination therapy is antitumorigenic in tissue recombination models from the Nkx3.1−/−; Pten−/− mutant mice. (A and I) Diagram of the experimental strategy. Tissue recombinants were made using prostate epithelium from Nkx3.1−/−; Pten−/− mutant or wild-type mice and rat embryonic mesenchyme and grown in nude mice for 1 month. Following 1 month of growth, the nude mice were either left intact (i.e., to model treatment of androgen-dependent prostate cancer) or castrated (i.e., to model treatment of androgen-independent prostate cancer). Mice received rapamycin and/or PD0325901 (or vehicle) for 21 days (5 days on/2 days off), following which the mice were sacrificed for analyses of end points (i.e., histology, prostate weights, and immunohistochemistry). (B–G and J–O) Representative tissue sections from the tissue recombinants made from the Nkx3.1−/−; Pten−/− prostate epithelium showing histological phenotype (H&E) and immunostaining for p-S6 and p-ERK, as indicated. Scale bars: 100 μm. (H and P) Weights of the tissue graphs, showing mean ± SEM, with P value indicated. Recomb, recombinant.
Although conventional chemotherapeutic approaches have been proven effective in many contexts, now including prostate cancer (5, 6, 38), it has become increasingly evident that ultimately the most effective and safest long-term treatment options for cancer patients will be achieved by targeting the specific networks that are deregulated in tumors, as exemplified by the now classic example of Gleevec for the treatment of leukemia (39). However, targeted therapies using single agents often lead to resistance, as also exemplified by Gleevec (40). It has been proposed that tumor resistance can be circumvented, at least in part, using agents in combination that can simultaneously target multiple pathways — the idea being that coordinate suppression of multiple pathways may minimize the chances of developing resistant tumor cells.

This general strategy of combination therapy requires knowledge of relevant signaling networks that are deregulated in particular cancers, an understanding of how their coordinate and/or cooperative activities contribute to tumorigenesis, and relevant in vivo model systems to test the functional consequences of therapeutic targeting of such pathways for tumorigenesis. Indeed, while informative analyses in tumor cells in culture may provide mechanistic insights, studies done in the context of the tumor microenvironment in the whole

Combination therapy is antitumorigenic in adjuvant therapy of hormone-refractory prostate cancer. (A–I) Studies in the whole animal. (A) Diagram of the experimental strategy. Strategy is similar to that in Figure 1; however, unlike the androgen-independent treatment group, Nkx3.1+/−Pten−/− mutant mice were castrated immediately prior to receiving the rapamycin and/or PD0325901 (or vehicle) treatment. (B–G) Representative tissue sections from the Nkx3.1+/−Pten−/− mutant mice showing histological phenotype (H&E) and immunostaining for p-S6 and p-ERK, as indicated. (H) Prostate tissue weights, showing mean ± SEM, with P value indicated. (I) Percentage of proliferating cells as determined by Ki67 staining, showing mean ± SEM, with P value indicated. (J–Q) Studies done in a complementary tissue recombination model. (J) Diagram of the experimental strategy. (K–P) Representative tissue sections from the tissue recombinants made from the Nkx3.1+/−Pten−/− prostate epithelium showing histological phenotype (H&E) and immunostaining for p-S6K and p-ERK, as indicated. (Q) Weights of the tissue graphs, showing mean ± SEM, with P value indicated. Scale bars: 100 μm.
organism are likely to provide more robust strategies for predicting the efficacy of combinatorial inhibition for tumor growth in vivo. In this regard, analyses of relevant genetically engineered mutant mouse models may be informative for predicting both the pathways that may be effectively targeted and the therapeutic efficacy of single and combinatorial inhibition of such pathways (41–44).

Indeed, our current analyses exemplify the value of this general approach, as we have effectively used the Nkx3.1; Pten mutant mouse model both to define the functional significance of the AKT/mTOR and ERK MAPK signaling pathways for prostate tumorigenicity and to demonstrate the profound antitumorigenic consequences of combinatorial inhibition of these pathways for prostate tumorigenicity. Importantly, our findings show that the combination therapy is considerably more effective than the single agents with respect to their antitumorigenic activity, which appears to reflect in part their effects on the expression of the apoptotic regulator Bim. Further insights regarding the mechanisms underlying the striking synergism of these pathways is provided by the accompanying article by Carracedo and colleagues, who report that these pathways are modulated by a negative feedback loop (45).

More generally, an important consideration when using combination targeted therapy is that, more so than for conventional chemotherapy, the efficacy of the treatment for any single individual is likely to depend upon whether the specific pathways are deregulated in tumors from such individuals. Thus, accurate evaluation of the efficacy of targeted therapies is likely to depend on knowledge of the status of the relevant pathways prior to the onset of treatment, since clinical success or failure may well depend upon the status of such pathways. Indeed, our findings showing that activation of relevant target proteins in the AKT/mTOR and/or ERK MAPK signaling pathways can be readily detected in primary tumors from human prostate cancer patients (see Figure 8) demonstrate the feasibility of this approach and provides an effective screening tool for both enrolling patients in clinical trials and evaluating the outcome of such trials.

androgens are unclear. Presumably, this reflects, at least in part, the combination therapy in prostate cancer in conditions of limiting chemotherapy with mechanism-based approaches (4).

The fact that these pathways may be preferentially activated in hormone-sensitive cancers, there may be mechanistic bases that are dependent on the tissue context, such as potential variations in the activity levels of these kinases in the presence or absence of androgens (46). Regardless, our findings showing the efficacy of this combination treatment when provided simultaneously with androgen ablation (Figure 7) raise the exciting possibility that combination therapy targeting AKT/mTOR and MEK/ERK MAPK signaling may even be effective in an adjuvant therapy model for hormone-refractory disease.

In summary, our findings as well as recent work by Stommel and colleagues and Shah and colleagues (47, 48) highlight the value of pursuing hypothesis-based preclinical studies in genetically engineered mutant mice that share relevant features with the human cancers that they represent.

### Methods

**Mouse models.** All experiments using mice were approved by the Institutional Review Board of Columbia University Medical College. The Nkx3.1;Pten compound mutant mice have been described previously (15, 17, 18). Preclinical studies were done in a mixed strain background (C57BL/6 × 129S/V) using cohorts assembled from littermates of wild-type (Nkx3.1+/+;Pten+/+) and mutant (Nkx3.1−/−;Pten−/− or Nkx3.1−/−;Pten−/−) mice at 10–12 months of age that had been housed together and subjected to identical environmental conditions. Mice were randomly assigned to the androgen-intact group or the androgen-independent group; the latter were surgically castrated to remove the testes and epididymis, which is the source of endogenous androgens. Tissue recombinants were made using prostate epithelium from mutant or wild-type mice and rat embryonic mesenchyme and grown in androgen-intact or androgen-deprived (castrated) nude male hosts, as described previously (15, 17).

**Preclinical trial design and analyses.** Rapamycin was purchased from LC Laboratories (catalog R-5000, lots ASW-105 and ASW-109); PD0325901 was a generous gift from Pfizer (Batch U). Rapamycin was dissolved in 100% ethanol to make a working stock of 25 mg/ml and then diluted to 1.25 mg/ml in a solution of 5.2% Tween-80, 5.2% PEG400 in sterile water and delivered i.p. at 10 mg/kg. PD0325901 was dissolved in 0.05% hydroxy-propyl-methylcel lulose, 0.02% Tween-80 in sterile water to make a working stock of 1.5 mg/ml and delivered via oral gavage at 20 mg/kg. Agents (or vehicle) were delivered for 5 consecutive days, with 2 days off for a period of 3 weeks. Mice were weighed daily and observed for signs of distress following dosing. Notably, none of the treatment paradigms resulted in appreciable weight loss (i.e., greater than 10%) in the mutant mice (Supplemental Table 1).

At the conclusion of the study, mice were sacrificed, prostate tissues were collected and photographed, and the wet weights of the prostate tissues were determined. For the tissue recombinant models, the graphs were removed from the kidney prior to weighing. The prostatic lobes (anterior, dorsolateral, and ventral) were collected individually and bilaterally; one lobe was fixed in formalin and paraffin-embedded for histology and immunohistochemistry and the other snap frozen in liquid nitrogen for Western blotting. All analyses were done using both the anterior and dorsolateral prostatic lobes; histological and immunohistochemical analyses are shown for the anterior prostate and Western blot analyses for the dorsolateral gland.

**Immunohistochemical studies.** Western blot analyses, and semiquantitative analyses of the histological phenotype were done as described previously (15, 17, 18). Briefly, for grading of the histological phenotype, a minimum of 4 random sections from different locations in the prostate tissues were examined for each experimental animal. The phenotype was scored based on analyses of the multiple sections in each animal plus the analyses of all animals, following which a representative tissue section was selected to illustrate the phenotype. Analyses of the immunohistochemical studies were done using 2–3 independent sections from each of 4 experimental animals in each group. For quantification of proliferating cells, slides were immunostained with Ki67, and cells were counted as described previously (49) in a minimum of 10 independent sections from 5 independent mice (i.e., 50 sections), with results expressed as the percentage of Ki67-labeled epithelium relative to total epithelium, visualized using hematoxylin.

Antibodies used in this study were: p-p44/42 MAPK (Thr202/Tyr204) antibody (catalog 9101 or IHC preferred antibody 4376; 1:200), p44/42 MAPK antibody (catalog 9102), p-AKT (Ser473) antibody (catalog 2927 or IHC preferred antibody 3787; 1:50), and p-56 Ribosomal Protein (Ser235/236) antibody (catalog 2211; 1:250), all from Cell Signaling Technology; Bim antibody (catalog 2065; 1:500) from ProSci Inc.; and NCL-Ki67p (1:1,500) from Novocastra (Leica Microsystems).

**Cell culture analyses.** Cytotoxicity assays were performed using the CASP 2.1 or 1.1 line (15, 19). Exponentially growing cells were seeded into 96-well plates at 800 cells/well in 100 μl growth medium in the presence or absence of dihydrotestosterone. Rapamycin or PD0325901 was serially diluted in media, and the cells were maintained at 37°C for 96 hours. Cell density was determined following addition of 20 μl MTS reagent (Promega) by measurement of the absorbance at 490-nm wavelength. The IC50 was deter-

Furthermore, our analyses of pathway activation in human prostate cancer have shown that a large percentage of advanced tumors display activation of AKT/mTOR and/or ERK MAPK signaling networks and predict that a large percentage of prostate cancer patients (>20%) will be appropriate candidates for treatment with agents that target these signaling pathways. Extrapolating from preclinical trials in the Nkx3.1;Pten mutant mice to the design of relevant clinical trials, we infer that combination therapy targeting AKT/mTOR and ERK MAPK signaling should be optimal for patients with hormone-refractory disease. Conceivably, combination therapy may be effective when used in conjunction with chemotherapy, as there are now several ongoing trials combining chemotherapy with mechanism-based approaches (4).

mined using the software SoftMax (Molecular Devices). For combination drug treatment, rapamycin plus PD0325901 was diluted in the growth medium at a fixed ratio of doses (IC50 versus IC50). The CI was calculated based on the Chou-Talalay equation (34) using CalcuSyn software (Bio-soft). For Bim-knockdown studies, CASP 1.1 and 2.1 cells were transfected with 50 nM of control or Bim siRNA (Santa Cruz Biotechnology Inc.), according to the manufacturer’s protocol. One day after transfection, cells were treated with rapamycin and/or PD0325901 for 48 hours. Cytotoxicity assays were performed using a Cell Growth Determination Kit, MTT Based (Sigma-Aldrich), according to the manufacturer’s protocol.

Human TMAs. The human TMAs were made using samples from prostatectomy specimens obtained from the Molecular Pathology Tumor Bank of Columbia University. All studies of human tissue were approved by the Institutional Review Board of Columbia University Medical Center. To construct the TMAs, sections of normal prostate and tumor tissue that were embedded in paraffin and stained with H&E were reviewed to identify viable, morphologically representative areas of the specimen from which needle core samples could be taken. From each specimen, triplicate tissue cores with diameters of 0.6 mm were punched and arrayed onto a recipient paraffin block using a precision instrument (Beecher Instruments). Five-micrometer sections of these TMA blocks were stained with H&E or used for immunohistochemical analysis. Prostate tumor samples included PIN and PCa, which was classified as having either a low Gleason (≤6) or high Gleason (>7) score.

Two TMAs were used for the present study. The first included 70 prostate samples: 25 BPH cases, 7 PIN lesions, and 38 PCa (19 displayed a low Gleason score and 19 a high Gleason score). Each tissue was represented by 3 independent cores in each TMA. The second TMA included 535 prostate samples: 65 corresponded to BPH, 78 to PIN, and 392 to PCa (181 cases corresponded to organ-confined prostate cancer, 120 cases to hormone-refractory prostate cancer, and 91 cases to metastatic prostate cancer). Seven consecutive sections of the 2 TMAs were cut and stained with H&E (verification of histopathology), used as a negative control, or stained with immunohistochemical markers.

Immunohistochemical analyses were performed following the standard avidin-biotin immunoperoxidase staining procedure. Briefly, TMA slides were deparaffinized and then submitted to antigen retrieval by steamer (verification of histopathology), used as a negative control, or stained with immunohistochemical markers.

Immunohistochemical analyses were performed following the standard avidin-biotin immunoperoxidase staining procedure. Briefly, TMA slides were deparaffinized and then submitted to antigen retrieval by steamer for 15 minutes in 10 mM citrate buffer at pH 6.0, followed by primary antibody incubation overnight at 4°C. Then slides were incubated with biotinylated anti-rabbit or anti-mouse immunoglobulins at 1:1,000 dilution for 30 minutes (Vector Laboratories Inc.) followed by avidin-biotin peroxidase complexes at a 1:25 dilution (Vector Laboratories Inc.) for 30 minutes. Diaminobenzidine was used as the chromogen and hematoxylin as a nuclear counterstain. Primary antibodies used were against PTEN (Ab-6, mouse clone 6H2.1; Neomarkers, Thermo Scientific; 1:50), p-AKT (Ser473, rabbit polyclonal; Cell Signaling Technology; 1:50), p-mTOR (Ser2448, rabbit clone 49F9; Cell Signaling Technology; 1:50), S6K (rabbit polyclonal; Cell Signaling Technology; 1:75), and p44/42 MAPK (rabbit clone 137F5; Cell Signaling Technology; 1:100).

The immunoreactivity for each antibody was scored according to the proportion of cells displaying a positive immunostaining profile (from undetectable [0%] to homogeneous expression [100%]) and the intensity of the staining (0, 1+, 2+, 3+). Average values of the 3 representative cores from each arrayed sample were used for statistical analyses. Expression values were displayed as mean values accompanied by 95% confidence intervals and range. The relationship between immunohistochemical results and clinical parameters was analyzed using the nonparametric Wilcoxon–Mann–Whitney U tests. A P value of less than 0.05 was considered statistically significant.

Acknowledgments

We are indebted to Pfizer for sharing the PD325901 compound. We thank Mitchell Benson, Edward Gelmann, Daniel Petrylak, and Michiel Shen for comments on the manuscript. This work was supported in part by National Cancer Institute (NCI) grants to C. Abate-Shen (U01-CA84294 and R01-CA115717), as well as funding from the T.J. Martell Foundation. C. Cardon-Cardo and his laboratory are, in part, supported by the NCI SPORE CA92629 grant in Prostate Cancer and grants from The T.J. Martell Foundation and the Sands Family Foundation. A. Puzio-Kuter was supported by 1F31CA110625-01 Ruth L. Kirschstein National Research Service Award. T.H. Foster was supported in part, by the Swiss National Science Foundation (81BS-69441) and the Swiss Urologic Association.
