Lysosomal \(\beta\)-glucuronidase regulates Lyme and rheumatoid arthritis severity

Kenneth K.C. Bramwell, …, Cory Teuscher, Janis J. Weis

Lyme disease, caused by the spirochete \textit{Borrelia burgdorferi}, is the most prevalent arthropod-borne illness in the United States and remains a clinical and social challenge. The spectrum of disease severity among infected patients suggests that host genetics contribute to pathogenic outcomes, particularly in patients who develop arthritis. Using a forward genetics approach, we identified the lysosomal enzyme \(\beta\)-glucuronidase (GUSB), a member of a large family of coregulated lysosomal enzymes, as a key regulator of Lyme-associated arthritis severity. Severely arthritic C3H mice possessed a naturally occurring hypomorphic allele, \(Gusb^h\). C57BL/6 mice congenic for the C3H \(Gusb\) allele were prone to increased Lyme-associated arthritis severity. Radiation chimera experiments revealed that resident joint cells drive arthritis susceptibility. C3H mice expressing WT \(Gusb\) as a transgene were protected from severe Lyme arthritis. Importantly, the \(Gusb^h\) allele also exacerbated disease in a serum transfer model of rheumatoid arthritis. A known GUSB function is the prevention of lysosomal accumulation of glycosaminoglycans (GAGs). Development of Lyme and rheumatoid arthritis in \(Gusb^h\)-expressing mice was associated with heightened accumulation of GAGs in joint tissue. We propose that GUSB modulates arthritis pathogenesis by preventing accumulation of proinflammatory GAGs within inflamed joint tissue, a trait that may be shared by other lysosomal exoglycosidases.

Lyme disease, caused by the spirochete *Borrelia burgdorferi*, is the most prevalent arthropod-borne illness in the United States and remains a clinical and social challenge. The spectrum of disease severity among infected patients suggests that host genetics contribute to pathogenic outcomes, particularly in patients who develop arthritis. Using a forward genetics approach, we identified the lysosomal enzyme β-glucuronidase (GUSB), a member of a large family of coregulated lysosomal enzymes, as a key regulator of Lyme-associated arthritis severity. Severely arthritic C3H mice possessed a naturally occurring hypomorphic allele, Gusb⁺. C57BL/6 mice congenic for the C3H Gusb allele were prone to increased Lyme-associated arthritis severity. Radiation chimera experiments revealed that resident joint cells drive arthritis susceptibility. C3H mice expressing WT Gusb as a transgene were protected from severe Lyme arthritis. Importantly, the Gusb⁺ allele also exacerbated disease in a serum transfer model of rheumatoid arthritis. A known GUSB function is the prevention of lysosomal accumulation of glycosaminoglycans (GAGs). Development of Lyme and rheumatoid arthritis in Gusb⁺–expressing mice was associated with heightened accumulation of GAGs in joint tissue. We propose that GUSB modulates arthritis pathogenesis by preventing accumulation of proinflammatory GAGs within inflamed joint tissue, a trait that may be shared by other lysosomal exoglycosidases.

Introduction

Lyme disease, caused by the spirochete *Borrelia burgdorferi* (1), is the most prevalent arthropod-borne illness in the United States. More than 30,000 cases are reported each year, while estimates suggest that around 300,000 are diagnosed annually (2, 3). Disease severity varies greatly among the affected population, with up to 60% of untreated patients developing a self-limiting, inflammatory arthritis (4, 5). Even following appropriate antibiotic therapy, up to 10% of patients will develop chronic arthritis, which can persist for months to years. While the genetic composition of the spirochete is a critical determinant of the invasive potential of the bacteria (6), other host-associated attributes are also clearly instrumental in determining the severity and duration of symptoms of infection. Polymorphisms in TLR1 and -2 have been linked to altered innate immune responses to *B. burgdorferi*, providing strong evidence that host factors contribute to clearance of the pathogen and modulation of innate defenses, both early and late in infection (7–9). However, these polymorphisms do not explain the extent of disease manifestation in infected patients. The strong familial association of other types of arthritis is consistent with the concept that genetic predisposition may trigger a pathological response to inflammatory stimuli, such as bacterial infection. Furthermore, certain of the MHC alleles associated with rheumatoid arthritis (RA) have been identified as contributing to antibiotic-refractory Lyme arthritis by some groups, suggesting the possibility of other common mechanisms in immune-mediated stages of disease (10–12).

In a seminal observation, Barthold and colleagues reported that inbred strains of laboratory mice exhibit consistent differences in arthritis severity following infection with *B. burgdorferi*, and identified the C3H/HeJ or C3H/HeN (C3H) mouse as displaying the most severe disease and C57BL/6 (B6) as displaying less severe disease (13). Key features of arthritis development that are shared between infected C3H mice and patients with severe Lyme arthritis include synovial hyperplasia, inflammatory cell infiltrate, and exuberant edema. The mouse is one of the major mammalian reservoirs for *B. burgdorferi*, serving as host for blood meals of the larval and nymphal stages of *Ixodes spp* vector ticks (14). Studies in the mouse have been critical to our understanding of environmentally regulated changes in gene expression necessary for transition between hosts and the elaborate mechanism of antigenic variation necessary for survival in the immunocompetent host (15).

The imperative health need for understanding the genetic component of human Lyme arthritis prompted us to pursue a forward genetic approach to identify genes responsible for disease severity. Barthold’s initial studies (13) identified C3H and B6 as being at the extreme ends of Lyme disease symptoms, and more recent SNP-based analysis has placed B6 and C3H mice on well-separated branches of the mouse family tree (16). B6 is the reference strain for the mouse genome sequence, and C3H mice were included in the Perlegen Sciences resequencing project, permitting the extensive analysis of variation between these strains. Our work is the outcome of a classic forward genetic approach to identifying regulators of Lyme arthritis severity in mice. Intercross populations between C3H and B6 (or BALB/c) mice led to the identification of multiple *B. burgdorferi* arthritis–associated (*Bhaa*) quantitative trait loci (QTL) on 5 chromosomes (17). Four individual crosses identified *Bhaa2* on mouse chromosome 5, which exhibits the strongest linkage to disease severity, with a maximum lod score of 10.2 (18). Our laboratory previously developed a B6.C3H-Bhaa2Bhaa3 congenic mouse line, where *Bhaa2Bhaa3* from susceptible C3H mice was isolated on an otherwise uniform resistant B6 genetic background (19, 20), and found that these mice exhibit increased Lyme arthritis severity, with joint inflammation and histopathology closely resembling the human disease.
Figure 1
Positional mapping and characterization of the Gusb\textsuperscript{a} allele. (A) Advanced congenic lines identify regulatory subintervals within Bbaa2. Each row represents the genetic makeup of 1 congenic mouse line across the Bbaa2 interval (120.3 to 141.2 Mb) on mouse chromosome 5. White and black portions of each row represent areas inherited from the B6 or C3H background, respectively. Ankle swelling measurements taken 4 weeks after B. burgdorferi infection (n = 12 to 35 mice per group; overall P < 0.0001). Significance of cosegregation (right) between ankle swelling and blinded scores of joint histopathology and PMN infiltration, assessed by 1-tailed Mann-Whitney test. (B) Inheritance of the Gusb polymorphism among strains included in the Sanger SNP resequencing database. (C) C3H mice and congenics carrying the Gusb\textsuperscript{h} allele exhibited enzymatic hypomorphism in serum and bone marrow–derived macrophage cell extracts and supernatants (n = 4). (D) CBA/Ca expressed near normal serum GUSB activity, while CBA/J shared the C3H GUSB hypomorphism. (E) CBA/J developed severe Lyme arthritis, while CBA/Ca were resistant (n = 5 [B6 and C3H] and 10 [CBA substrains] mice in each group; overall P < 0.0001). Significance assessed by 1-way ANOVA followed by Dunnet’s multiple comparison test versus B6 (A and E) or Bonferroni’s post test (C and D). *P < 0.05; **P < 0.01; ***P < 0.001; ****P < 0.0001.
In this study, we report the positional cloning of a key genetic regulator underlying the increased Lyme arthritis severity conferred by Bbaa2 in C3H mice, the lysosomal enzyme β-glucuronidase, Gusb. The hypomorphic C3H allele, Gusb h, was found to cause increased arthritis severity in mouse models of both Lyme and rheumatoid arthritis. Gusb belongs to a recently recognized group of lysosomal enzymes that modulate lysosomal storage and function and that are coregulated in response to stress. We propose that mild deficiencies in Gusb and other coregulated lysosomal enzymes may have previously unrecognized impact on a variety of inflammatory pathologies.

**Results**

**Positional cloning of Gusb.** Through additional backcrossing to the parental B6 line, we developed 15 advanced B6.C3H-Bbaa2 congenic mouse lines harboring subintervals of Bbaa2 C3H from 120.3 to 141.2 Mbp (Figure 1A and ref. 21). After infection with B. burgdorferi, the various subinterval congenic lines exhibited a wide spectrum of disease severity, as assessed quantitatively by ankle swelling measurements. Compared with B6, congenic mice harboring C3H-derived intervals from 129.0–130.5 Mbp (P < 0.01), 133.5–141.2 Mbp (P < 0.05), and 125.3–128.2 Mbp (P < 0.05) within Bbaa2 exhibited significantly more severe disease. The ankle swelling data also support the presence of a negative regulatory element within Bbaa2 (Supplemental Figure 1; supplemental material available online with this article; doi:10.1172/JCI72339DS1). Moreover, for the 129.0–130.5 Mbp and 133.5–141.2 Mbp intervals, increases in the categorical traits of pathology score and neutrophil (PMN) infiltration cosegregated with ankle swelling. Consequently, they have been designated Bbaa2a and Bbaa2b, respectively. Bbaa2a sequence analysis revealed a high degree of conservation between B6 and C3H mice, exhibiting very low SNP density (21). This interval contains 24 genes (Supplemental Figure 2), none of which are differentially expressed at the transcriptional level between B6 and C3H mice following infection, as measured by microarray analysis (20). The Sanger SNP resequencing database (22) indicates that the interval harbors only 1 high-confidence coding nonsynonymous G→A polymorphism differing between B6 and C3H strains, which causes a T87I amino acid change in the ubiquitously expressed lysosomal enzyme Gusb (Figure 1B).

**Figure 2**

Loss of GUSB function exacerbates Lyme arthritis severity in a genetically recessive manner. (A) GusbNull mice do not exhibit a defect in host defense. The observed difference between B6 and C3H genetic backgrounds in heart bacterial burden has been previously described (59). (B) Serum GUSB activity of infected B6 and C3H controls, GusbNull homozygotes, and GusbNull heterozygous littermates (n = 5 to 6 per group). (C) Arthritis severity measurements of GusbNull homozygotes, heterozygous littermates, and WT B6 and C3H controls (n = 5 to 6 per group; overall P < 0.0001). (D and E) Arthritis severity measurements of B6.C3H-Bbaa2 and B6.C3H-GusbNull heterozygotes were statistically indistinguishable from B6 control animals (n = 5 per group; overall P < 0.001). Significance assessed by 1-way ANOVA followed by Bonferroni’s multiple comparison test versus B6. *P < 0.05; ***P < 0.001; ****P < 0.0001.
The C3H strain is known to carry a functionally hypomorphic \textit{Gusb} \textit{h} allele, which confers a 70\%–90\% reduction in enzymatic activity in the serum and various tissues (23, 24). We verified that our B6.C3H-Bbaa2 congenic mice exhibited hypomorphic GUSB enzymatic activity in serum and in cell extracts and supernatants obtained from strain-specific bone marrow–derived macrophages (Figure 1C). We observed no significant differences in \textit{Gusb} mRNA levels between strains or following \textit{B. burgdorferi} infection, indicating that this hypomorphism manifests posttranscriptionally (Supplemental Figure 3). The Sanger SNP database indicates that only 3 of the 18 included strains, C3H/HeJ, AKR/J, and CBA/J, share this \textit{Gusb} coding variant. Both C3H and AKR/J have previously been shown to develop severe Lyme arthritis (13, 25). Intriguingly, the lower density CDG-MDA1 database shows that unlike CBA/J, a closely related CBA/Ca strain functions as a lysosomal hydrolase that requires the low pH of the lysosome for full enzymatic activity, but is also present in these heterozygous animals.

\textit{GUSB} hypomorphism acts through a cell-intrinsic mechanism. GUSB functions as a lysosomal hydrolase that requires the low pH of the lysosome for full enzymatic activity, but is also present in these heterozygous animals.
Notably, the disease severity of the B6→B6.C3H-Bbaa2 group was increased despite high GUSB activity levels in the serum. Conversely, B6.C3H-Bbaa2→B6 chimeric mice did not develop significantly more severe disease than the B6→B6 control group, despite low serum GUSB activity. These results indicate that GUSB hypomorphism primarily modulates disease severity within joint-resident, radiation-resistant cells and that serum GUSB levels are not determinative. This suggests that GUSB hypomorphism acts through a localized, cell-intrinsic mechanism to initiate the development of inflammatory arthritis.

Transgenic overexpression of Gusb in C3H mice reduces Lyme arthritis severity. Because Gusb does not appear to interfere with the function of Gusb in a dominant negative fashion in our various heterozygous experiments and because our radiation chimera experiments implicate joint resident cell types in arthritis development, transgenic overexpression to correct GUSB levels in a hypomorphic strain was considered a reasonable approach. To determine the magnitude of the Gusb effect, a transgenic driving ubiquitous mouse Gusb expression (Figure 4A) was used to produce C3H/HeN-CAG-Gusb transgenic mice (GusbTg). Five founders were identified that met or exceeded the serum GUSB enzymatic activity level achieved ubiquitously in all tissues. Following infection with B. burgdorferi, we found that GusbTg progeny exhibited a profound and highly significant (P < 0.001) reduction in disease severity (Figure 4C) relative to WT C3H control mice. This argues that among the many Bbaa loci previously identified to regulate Lyme arthritis severity in C3H mice, Gusb is a key regulator.

Evidence of a conserved role for Gusb in a model of rheumatoid arthritis. Because the B6.C3H-Gusb congenic line provides the greatest genetic stringency to interrogate the specific impact of GUSB hypomorphism on a resistant genetic background, we used it to determine whether alterations in Gusb modulate disease severity in a way that is unique to Lyme arthritis or whether it plays a more generalized role. To test this, we used the K/BxN serum transfer model of rheumatoid arthritis as a second experimental approach to inducing disease (30, 31). This model isolates the downstream effector phase of disease pathogenesis from the initiation phase through adoptive transfer of arthritogenic autoantibodies to induce a joint-specific inflammatory arthritis. Injection of submaximal doses of K/BxN serum was useful in determining the unique contribution of Gusb to arthritis severity in this model. Following intraperitoneal injections of 100 μl K/BxN serum on days 0 and 2, we found that our B6.C3H-Gusb congenic mice began to exhibit more severe ankle swelling than B6 control animals beginning on day 4, which was further exacerbated on day 7 (Figure 5A). Histopathology scores for joints at day 7 also corroborated the significance (P < 0.05) of this effect (Figure 5B).

GUSB deficiency is associated with excessive accumulation of glycosaminoglycans during arthritis development. GUSB is a lysosomal hydrolase that catalyzes an essential step in the homeostatic degradation of glycosaminoglycans (GAGs). Severe autosomal recessive GUSB deficiency causes a lysosomal storage disease known as MPSVII, one characteristic of which is spontaneous accumulation of partially degraded GAGs within lysosomes (32). C3H mice begin to develop mild lysosomal accumulation of GAGs by 12 months of age, but younger 9- to 11-week-old mice appear to be unaffected (33). GAGs and partially degraded fragments have previously been implicated as direct mediators of inflammation through activation of TLRs (34). Rodent models of lysosomal storage disease have been shown to exhibit less severe symptoms following the genetic removal of TLR4 or the pharmacological blockade of TNF-α signaling, consistent with an inflammatory component to disease pathogenesis (35, 36). To determine whether GAG accumulation occurs during arthritis development in our GUSB-deficient strains, we performed Alcian blue staining to detect the presence of acidic polysaccharides, including GAGs, in joint histopathology sections at 4 weeks after infection. The inflamed tissues from Gusb and Gusb mice consistently stained intensely positive for the presence of GAGs. Alcian blue-positive material was identified in the perivascular soft tissue, particularly the tendon sheath, of the joints of Gusb and Gusb strains (Figure 6, B, D, F, and H). GAG accumulation was associated with severe tendonitis manifested by acute inflammation composed of dense neutrophilic infiltrates, tendon hyperproliferation, and synovial hypertrophy. In contrast, no significant accumulation of Alcian blue-positive material or inflammation was detected in joints from C3H Gusb and other GUSB-sufficient strains (Figure 6, A, C, E, and G). Similarly, joints from day 7 K/BxN-treated B6 control animals lacked GAG accumulation despite
It is well established that mutations causing frank deficiencies in GUSB result in spontaneous and overt lysosomal storage disease, although mild deficiencies may go unrecognized until late in life and are often misdiagnosed as an inflammatory joint disease (37). Human GUSB is known to be polymorphic, with over 750 SNPs recorded in the dbSNP database. Forty-nine mutations causing overt disease have been identified in MPSVII patient populations (32), while the prevalence and impact, if any, of other variants remain undefined. Human GUSB enzymatic activity levels in the general population have been shown to exhibit a wide distribution and vary in tissue and serum samples by up to 30-fold (38, 39), differenting larger than those observed between high-expressing (B6, CBA/Ca) and low-expressing (C3H, CBA/J) inbred mouse strains used in this study (Figure 1D and ref. 33). GUSB may be uniquely sensitive to mild deficiencies in enzymatic activity; since it has been suggested as the rate-limiting enzyme in the dermatan sulfate degradative pathway (40). Severe deficiencies in individual lysosomal enzymes causing overt disease are rare, with a combined incidence estimated at up to 1 in 5,000 births (41), far below the practical limit of detection of genome wide association studies (GWAS) (minor allele frequency > 0.05) (42). Although human genetic susceptibility to Lyme arthritis has not been investigated by GWAS, it is noteworthy that thus far only a fraction of the genetic variance underlying rheumatoid arthritis has been identified by GWAS (43), accentuating the added value of our QTL mapping approach.

Our studies have identified a naturally occurring, mild subclinical GUSB deficiency that transforms the normally protective local response to B. burgdorferi into a fulminating inflammatory arthritis. Recent literature has brought attention to the persistence of bacterial antigen in host tissues, even following antibiotic regimens that effectively cleared cultivable bacteria (44). Importantly, the increased disease severity we have observed occurs in the absence of significant alterations in host defense or inflammatory initiators such as B. burgdorferi antigen or autoantibodies trigger severe disease through a 2-hit phenomenon, where coincident breakdown of host tolerance mechanisms designed to limit the pathological consequences of infection and the ensuing inflammatory response instead exacerbate disease symptoms. The ability of GUSB to exacerbate arthritis in response to very different experimental stimuli suggests this phenomenon may also be generalizable to other inflammatory triggers.

Our observation that radiation-resistant, joint-resident cells are a primary determinant of the magnitude of the Lyme arthritis response offers important insight into the mechanisms underlying joint pathogenesis in this model. This finding indicates that resident cells have important roles both in recruiting inflammatory immune cells to help clear infection and in mitigating damage through tolerance mechanisms. Our complementary finding that the severe joint pathology observed in infected B6.C3H-Bhats2 mice is not effectively corrected by high-serum GUSB levels bears striking resemblance to reports on the limited efficacy of enzyme replacement therapy to alleviate musculoskeletal symptoms in adult animal models of MPSVII (45, 46), although early intervention in neonates has shown promise (47, 48). Similarly, the joint pathologies in patients with a variety of mucopolysaccharidoses are difficult to treat and respond...
much more slowly to high-dose enzyme replacement therapy than other symptoms, such as hepatosplenomegaly or sleep apnea (49). Taken together, these findings highlight the importance of the primary response to bacterial stimulation that is mounted by resident cells in these refractory joint tissues.

The evident link between GUSB hypomorphism and excessive deposition of GAGs with potential proinflammatory activity provides a plausible mechanism bridging disease to the critical catalytic role GUSB plays in homeostatic GAG degradation. Although our data show no significant change in bacterial load due to GUSB deficiency, GAG-mediated cell adhesion by *B. burgdorferi* does play a noteworthy role in mammalian infection and tissue localization (50). The GUSB substrate dermatan sulfate has been linked to excessive TNF-α release by chondrocytes (40), and MPSVI symptoms are alleviated by blocking TNF-α (36), a highly successful target for rheumatoid arthritis (51). However, this does not preclude the involvement of other downstream effectors. The release and accumulation of lysosomal exoglycosidases in the serum has been observed in multiple forms of chronic inflammatory arthritis, with localized release into synovial fluid reported to be especially exaggerated in chronic Lyme arthritis patients (52, 53). Although lysosomal exoglycosidases such as GUSB are catalytically inactive at neutral pH, coincident release of other proinflammatory lysosomal components may provide an alternate mechanism to trigger or amplify a local inflammatory cascade (54).

We suggest that the identification of *Gusb* as a key regulator of murine Lyme and rheumatoid arthritis severity provides a sound scientific basis for future investigations into serum GUSB or GAG levels as potential biomarkers of human susceptibility to developing chronic or severe inflammatory arthritis.

*Gusb* is 1 member of a large group of over 40 coregulated lysosomal enzymes in the coordinated lysosomal expression and regulation (CLEAR) network that are responsible for the stepwise degradation of several distinct biological substrates, including GAGs, lipids, sugars, chitin, and glycogen (55). As with *Gusb*, severe deficiencies in virtually all of these enzymes induce spontaneous lysosomal storage disease. Many such lysosomal storage diseases exhibit progressive joint disease. Recent work has demonstrated that overexpression of the master regulatory transcription factor of the CLEAR network, TFEB, leads to successful clearance of glycogen from lysosomes in both in vitro and mouse models of Pompe disease (56). Based on the close regulatory and functional interrelationship between *Gusb* and other lysosomal enzymes, we propose that the increased arthritis severity observed in this study may also be generalizable to mild deficiencies in other members of the CLEAR network.

**Figure 6**

GUSB enzymatic hypomorphism is associated with exaggerated accumulation of GAGs in the inflamed joint. Representative images of Alcian blue–stained rear ankle joint sections from *B. burgdorferi*–infected GUSB-sufficient (upper panels: A, C, E, and G) or GUSB-deficient (lower panels: B, D, F, and H) strains, or day 7 K/BxN-treated B6 (I) and B6.C3H-*Gusb* (J) congenic mice. Arrowheads indicate position of the cranial tibial tendon sheath. Original magnification, ×4. Scale bars: 500 μm (K) GAG accumulation in the soft tissue and joint/synovial space was scored on a scale of 0–4 (n = 3 to 4 joints per group). Pairwise significance assessed by 1-tailed Mann-Whitney test. *P* < 0.05.
Methods

Generation of interval-specific congenic lines

Interval-specific congenic lines (ISCL) were generated as described (19). Standard nomenclature for the mouse lines is used herein, as follows: the background strain (e.g., C57BL/6Ncr, abbreviated B6 in the ISCL designations) is listed first, followed by the donor strain (e.g., C3H) and the introgressed interval on mouse chromosome 5 (in Mb, according to the NCBI37/mm9 Mouse Genome Assembly) from C3H/HeNcr into the C57BL/6Ncr parental strain (National Cancer Institute). B6.C3H-120.3-141.2 (Full Length, B6.C3H-Bbaa2), B6.C3H-120.3-121.6, B6.C3H-120.3-125.6, B6.C3H-120.3-126.6, B6.C3H-120.3-128.2, B6.C3H-125.3-128.2, B6.C3H-125.3-131.0, B6.C3H-125.3-131.8, B6.C3H-129.0-130.5 (B6.C3H-Gusb+), B6.C3H-129.0-141.2, B6.C3H-131.8-133.5, B6.C3H-131.8-141.2, B6.C3H-134.7-141.2, and B6.C3H-136.4-141.2 ISCL were generated by marker-assisted selection using high-resolution melting analysis SNP genotyping primers as described (21). Homozygous progeny derived from matting heterozygous male and female ISCL mice that were free of background donor strain contamination were used to fix the lines.

GusbbNull mice

GusbbNull mice were obtained from Jackson Laboratory, as a mouse model of MPSVII. GusbbNull mice were derived from heterozygous breeder pairs, and homozygous offspring were identified at markedly sub-Mendelian ratios (data not shown) by SNP genotyping and reduced body size. As per Jackson Laboratory documentation, this spontaneous mutant mouse line originally derived from C3H/HeN mice (National Cancer Institute). B6.C3H-120.3-141.2 (Full Length, B6.C3H-Bbaa2), B6.C3H-120.3-121.6, B6.C3H-120.3-125.6, B6.C3H-120.3-126.6, B6.C3H-120.3-128.2, B6.C3H-125.3-128.2, B6.C3H-125.3-131.0, B6.C3H-125.3-131.8, B6.C3H-129.0-130.5 (B6.C3H-Gusb+), B6.C3H-129.0-141.2, B6.C3H-131.8-133.5, B6.C3H-131.8-141.2, B6.C3H-134.7-141.2, and B6.C3H-136.4-141.2 ISCL were generated by marker-assisted selection using high-resolution melting analysis SNP genotyping primers as described (21). Homozygous progeny derived from matting heterozygous male and female ISCL mice that were free of background donor strain contamination were used to fix the lines.

Generation of C3H/HeN-CAG-Gusbb transgenic mice

All PCR steps were performed for 25 cycles with high-fidelity Phusion Taq DNA Polymerase (Thermo Scientific) in 1× HF buffer, following the manufacturer’s recommendations, on a LightCycler 480 Platform (Roche Applied Science).

All agarose gel electrophoresis steps were performed with 1% agarose gels in 1× TBE buffer (89 mM Tris base, 89 mM boric acid, 2 mM EDTA), unless otherwise specified.

All band visualization was performed by ethidium bromide staining on a Gel Doc XR+ platform (Bio-Rad Laboratories).

All agarose gel purification steps were performed with a GenJet Gel Extraction kit (Fermentas), according to the manufacturer’s recommendations, unless otherwise specified.

Gusbb insert preparation. The open reading frame of the cDNA coding sequence from MGC cDNA clone 78180 (IMAGE:5325429) was PCR amplified with an annealing temperature of 71 °C. The following sequence-specific primers containing 5′ EcoRI cloning sites produced approximately 2000-bp ampiclon: mgusbORF-forward, CCGG-TAGAATTCTAGTCCCTAATTGAGGTGGTGT, mgusbORF-reverse, CCGGGTGAATTTCTTAGAACGTTGACGGTCTGCTTCC. The PCR product was incubated with EcoRI restriction enzyme for 1 hour at 37°C, then separated by agarose gel electrophoresis. A band of the predicted size was visualized, excised, and gel purified.

pCAGGS transgenic. A mammalian overexpression construct previously shown to drive high-level expression of human GUSB in mice (58) was provided by Mark Sands (Washington University, St. Louis, Missouri, USA). The human Gusb cDNA insert was removed by cleavage with EcoRI, releasing a 2.2-kb fragment of the predicted size, which was then separated from the backbone by agarose gel electrophoresis. The backbone was excised and gel purified. The purified Gusb ORF fragment was cloned into pCAGGS EcoRI and validated by fully sequencing across the insert.

Purification of the CAG-Gusbb fragment. The transgenic fragment was removed from the backbone by cleavage with Earl and SpeI restriction enzymes and separated by electrophoresis in 1× TAE buffer on a 1% agarose gel. The approximately 4174-bp fragment was excised, removed from the gel slice by electroelution in 3 ml of 1× TAE buffer run at 100 volts for 1 hour. The fragment was then purified using an ELUTIP column (Whatman) according to the manufacturer’s recommendations and resuspended in low EDTA-TE injection buffer (10 mM Tris/0.1 mM EDTA pH 7.5). 2 μg of the purified fragment was provided to the University of Utah Transgenic and Gene Targeting Mouse Core Facility for microinjection into embryos derived from C3H/HeN mice (National Cancer Institute).

A total of 43 mice were screened for presence of the Gusbb transgene by PCR genotyping of genomic DNA using intron-spanning primers: forward, 5′-CCACGGCAATAAGGTCCGGAG-3′, reverse, 5′-GGCCCAAGTTCTGAGGACATGCG-3′. They were also screened for serum GUSB activity levels, normalized to β-galactosidase activity as an internal control (Figure 4B).

GUSB enzymatic activity assay

4-Methylumbelliferyl β-D-glucuronide (MUG) (Marker Gene) was used as a fluorogenic substrate to measure GUSB enzymatic activity. 10 μl of sample (serum, cell extract, or supernatant) was incubated with 1 mM MUG in a total volume of 50 μl assay buffer (200 mM sodium acetate; pH 4.5; 10 mM EDTA; 0.01% BSA; 0.1% Triton X-100) for 1 hour at 37°C in a 96-well plate (#3370; Costar). 150 μl of stop buffer (200 mM sodium carbonate) was then added, and samples were analyzed on a Biotek Synergy HT microplate reader. Fluorescence was measured with an excitation wavelength of 360 nm and an emission wavelength of 460 nm. Units were calculated by comparison against a standard curve prepared using purified bovine liver glucuronidase (type B-1 #G0251; Sigma-Aldrich). Measurements of β-galactosidase activity were performed in a similar manner using 4-methylumbelliferyl β-D-galactopyranoside (Marker Gene) as a substrate.

Culture and analysis of bone marrow–derived macrophages

BMMøs were prepared as described (19) by culture in RPMI 1640 medium (Invitrogen) supplemented with 30% L929 conditioned medium and 20% horse serum (HyClone). Harvested macrophages were replated into 12-well plates at a density of 6 × 10^5/ml in medium lacking serum and containing 1% Nutridoma. Supernatants were harvested 24 hours later, cells were washed once with 1× PBS, and cell extracts were then harvested by incubation in extraction buffer (50 mM NaPO4, pH 7.0; 10 mM BME; 10 mM EDTA; 0.1% sarcosyl; 0.1% Triton X-100).

Culture of B. burgdorferi and infection of mice

Mice between 6 and 7 weeks of age were infected by intradermal injection with 2 × 10^8 bacteria of the B. burgdorferi N40 isolate (provided by Stephen Barthold, UCD, Davis, California, USA). B. burgdorferi cells were cultured in Barbour-Stoenner-Kelly II medium containing 6% rabbit serum (Sigma-Aldrich).

Arthritis analysis

Rear ankle joints were measured at the time of infection and at 4 weeks after infection by using a metric caliper, as described (19). Measurements of the thickest anteroposterior portion of the ankle with the joint extended were taken and are reported as the change in ankle swell-
ing over time. A histological assessment of arthritis severity was performed with the most swollen ankle joint. Tissues were fixed in 10% neutral buffered formalin, decalcified, embedded in paraffin, and cut into 3-μm–thick sections; sections were mounted onto glass slides and stained with H&E or with Alcian blue. The H&E-stained joint sections were evaluated blindly and scored for the severity of injury according to a subjective scale ranging from 0 to 5. A score of 0 indicated no lesions, and scores of 1, 2, 3, 4, and 5 indicated minimal, mild, moderate, marked, and severe lesions, respectively. The overall lesion score represented a combined assessment of neutrophil infiltration, mononuclear cell infiltration, tendon sheath thickness, and reactive-reparative responses. To assess GAG accumulation, joint sections from each group were given a subjective score based on the presence of Alcian blue–positive material in the soft tissue and joint/synovial space, ranging from 0 (none) to 4 (severe).

### Generation and analysis of radiation chimeras

Chimeras were generated in all pairwise combinations between B6 CD45.1 and B6.C3H-Bha2a2 (CD45.2) congenic mice as described (29). Briefly, 4-week-old mice were lethally irradiated with 2 doses of 525 cGy given 3 hours apart using a GE Isoliv Titan (GE Healthcare). 24 hours later, splenocytes were prepared from donor mice. Irradiated mice each received an intravenous injection of 2 × 10⁷ splenocytes in a 200 μl volume. Chimerism was evaluated at 3 weeks after transplant by flow cytometric analysis of blood leukocytes (Supplemental Figure 6).

### K/BxN serum transfer

K/BxN serum was a gift from Paul Allen (Washington University). Rear ankle joints were measured with a metric caliper prior to treatment, as described above. 100 μl of K/BxN serum was administered by intraperitoneal injections on days 0 and 2. Ankle swelling was determined by measurements on days 1, 2, 4, and 7. After the final day 7 measurement, joint histopathology was assessed, as described above.

### Imaging of joint histoity sections

Alcian blue–stained sections were visualized on an Olympus BX41 clinical microscope (Olympus America) using ×4 total magnification. Images were recorded with an Olympus DP72 camera and prepared using Olympus cellSens digital imaging software.

### Statistics

All data represent mean ± SEM. All statistical calculations were performed using GraphPad Prism 5. P < 0.05 was considered statistically significant. Continuous variables were analyzed by 1-way ANOVA and Student’s t-test. Categorical variables were analyzed by Kruskal-Wallis or Mann-Whitney nonparametric tests. All calculations of Student’s t-tests and Mann-Whitney tests are 2-tailed unless otherwise specified.

### Study approval

All study protocols involving mice were conducted in accordance with the NIH guidelines for the care and use of animals and approved by the Institutional Animal Care and Use Committee at the University of Utah.

### Acknowledgments

We thank Mark Sands (Washington University) for providing the pcAGG-β-gal mammalian expression plasmid that was used to create our transgenic overexpression construct. Paul Allen (Washington University) kindly provided K/BxN serum. The project described was supported by award T32AI055434 (to K.C. Bramwell), 6133/Arthritis Foundation (to K.C. Bramwell), AI32223/National Institute of Allergy and Infectious Diseases (NIAID) (to J.J. Weis), AR-43521/National Institute of Arthritis and Musculoskeletal and Skin Diseases (NIAMS) (to C. Teuscher and J.J. Weis), NS061014/National Institute of Neurological Disorders and Stroke (NINDS) (to C. Teuscher), AI041747/NIAID (to C. Teuscher), NS060901/NINDS (to C. Teuscher), NS036526/NINDS (to C. Teuscher), and NS069628/NINDS (to C. Teuscher). The DNA/Peptide Core is supported in part by Cancer Center Support grant P30 CA04201. We thank Lynn Sondergereg and Robert Lochhead for helpful discussions. The content is solely the responsibility of the authors and does not necessarily represent the official views of the NIH.
