Head morphogenesis requires complex signal relays to enable precisely coordinated proliferation, migration, and patterning. Here, we demonstrate that, during mouse head formation, taspase1-mediated (TASP1-mediated) cleavage of the general transcription factor TFIIA ensures proper coordination of rapid cell proliferation and morphogenesis by maintaining limited transcription of the negative cell cycle regulators p16\textsuperscript{Ink4a} and p19\textsuperscript{Arf} from the Cdkn2a locus. In mice, loss of TASP1 function led to catastrophic craniofacial malformations that were associated with inadequate cell proliferation. Compound deficiency of Cdkn2a, especially p16\textsuperscript{Ink4a} deficiency, markedly reduced the craniofacial anomalies of TASP1-deficient mice. Furthermore, evaluation of mice expressing noncleavable TASP1 targets revealed that TFIIA is the principal TASP1 substrate that orchestrates craniofacial morphogenesis. ChIP analyses determined that noncleaved TFIIA accumulates at the p16\textsuperscript{Ink4a} and p19\textsuperscript{Arf} promoters to drive transcription of these negative regulators. In summary, our study elucidates a regulatory circuit comprising proteolysis, transcription, and proliferation that is pivotal for construction of the mammalian head.
Taspase1-dependent TFIIA cleavage coordinates head morphogenesis by limiting Cdkn2a locus transcription

Head morphogenesis requires complex signal relays to enable precisely coordinated proliferation, migration, and patterning. Here, we demonstrate that, during mouse head formation, taspase1-mediated (TASP1-mediated) cleavage of the general transcription factor TFIIA ensures proper coordination of rapid cell proliferation and morphogenesis by maintaining limited transcription of the negative cell cycle regulators p16Ink4a and p19Arf from the Cdkn2a locus. In mice, loss of TASP1 function led to catastrophic craniofacial malformations that were associated with inadequate cell proliferation. Compound deficiency of Cdkn2a, especially p16Ink4a deficiency, markedly reduced the craniofacial anomalies of TASP1-deficient mice. Furthermore, evaluation of mice expressing noncleavable TASP1 targets revealed that TFIIA is the principal TASP1 substrate that orchestrates craniofacial morphogenesis. ChIP analyses determined that noncleaved TFIIA accumulates at the p16Ink4a and p19Arf promoters to drive transcription of these negative regulators. In summary, our study elucidates a regulatory circuit comprising proteolysis, transcription, and proliferation that is pivotal for construction of the mammalian head.

Introduction

Morphogenesis of mammalian heads is a complex process coordinating differential cell proliferation, death, migration, and patterning in all germ layers. Craniofacial malformations in humans are major congenital disorders and a primary cause of infant mortality (1, 2). More than 700 distinct human craniofacial anomalies have been described, including cleft lip, cleft palate, Treacher Collins syndrome, and holoprosencephaly. However, our knowledge of the genetic and environmental factors causing these anomalies is as yet very limited; this has hindered the development of effective treatments and preventative care for most of these anomalies.

Vertebrate animal models have been effective tools for understanding the conserved molecular processes governing head morphogenesis. In mammals, the prospective brain (anterior neuroectoderm) is induced by the anterior visceral endoderm and subsequently transforms into the anterior neural plate. Transcription factors, such as OTX2, LIM1, SSDP1, and HEX, and signaling pathways, such as WNT and BMP, define the complex network involved in this anterior specification (3–8). Upon neurulation, the anterior neural plate forms a neural tube that subdivides into 3 vesicles: the prosencephalon (forebrain), mesencephalon (midbrain), and rhombencephalon (hindbrain) (9). When neural progenitor cells increase in population, the brain vesicles experience robust size expansion, with a cell cycle time of 7 hours in the prosencephalon and 8.5 hours in more caudal regions (10, 11). Importantly, cell proliferation is tightly controlled during brain expansion (12, 13). Poor cell cycle regulation is associated with a variety of head malformations (1, 2). However, the specific cell cycle factors involved in craniofacial morphogenesis have remained obscure. Their discovery is challenging, likely due to functional redundancy, such that the null alleles of cyclins, cyclin-dependent kinases (CDKs), and CDK inhibitors (CDKIs) do not incur overt craniofacial defects (14, 15).

Site-specific proteolysis regulates a variety of physiological and cellular processes, including the activation of caspases for cell death execution and the cleavage of the Notch intracellular domain for cell fate determination (16). Taspase1 (TASP1; threonyl aspartase) is a 50-kDa endopeptidase of a family of hydro­lases possessing an asparaginase 2 homology domain (17, 18). Our initial genetic study of taspasel-null (Tasp1–/–) mice uncovered a critical role for TASP1 in cell cycle control (19). Tasp1–/– mice exhibited decreased overall body size; Tasp1–/– mouse embryonic fibroblasts (MEFs) exhibited impaired cell cycle progression, with upregulation of CDKIs p16ink4a, p21cip1, and p27kip1 and downregulation of Ccn1, Ccn2, and Ccnb (19). Bona fide TASP1 substrates with conserved IXQL(V)D/G cleavage site motifs include a ubiquitously expressed general transcription factor TFIIAα-β, a testis-enriched general transcription factor ALFa-β (TFIIA-like factor), histone methyltransferases H3L1 (also known as MLL) and MLL2 (also known as MLL4), and Drosophila HCF (19–22). We discovered that TASP1-mediated proteolysis activates the full histone methyltransferase activities of MLL1 and MLL2, which in turn target cyclin gene promoters via E2F transcription factors (19, 23). On the other hand, it remained unclear how TASP1 mediates the transcriptional regulation of CDKIs.

Figure 1. Craniofacial malformations observed in Tasp1–/– mice. (A) Frequencies of live WT, Tasp1+/–, and Tasp1–/– animals observed at the indicated developmental stages. The expected genotype percentages from this intercross are 25%, 50%, and 25% for WT, Tasp1+/–, and Tasp1–/–, respectively. The reduction of the Tasp1–/– frequency between E18.5 and P1 indicates perinatal lethality. (B) Frequencies of the head malformations in WT, Tasp1+/–, and Tasp1–/– P0 pups. Tasp1-deficient animals displayed a range of head and face deformities. (C) Images on the top row are representative Tasp1–/– pups exhibiting smaller eyes (microphthalmia), absence of eyes (anophthalmia), lack of jaw (agnathia), and rod-like nose (ethmocephaly) as well as complete absence of craniofacial structures anterior to the ears (acephaly). Scale bar: 2.0 mm. Images on the bottom row show malformation of skull derivatives. Skull structures are identified where indicated. bo, basioccipital bone; bs, basisphenoid; e, exoccipital bone; f, frontal bone; i, interparietal bone; mn, mandible; mx, maxilla; n, nasal bone; p, parietal bone; pm, premaxilla; s, supraoccipital bone; tp, temporal bone; tr, tympanic ring.

The critical step of mRNA transcription is the recruitment and assembly of a transcription preinitiation complex, which consists of RNA polymerase II and general transcription factors (TFIIA, TFIIH, TFIID, TFIIIE, TFIIF, and TFIIE) (24–26). TFIIA enhances transcription by stabilization of the binding of TATA-binding protein (TBP) at the promoter DNA and by counteracting the inhibitory effects of negative cofactors, like NC2/Drl and TAF1 (27–29). In higher eukaryotes, TFIIA exists as a heterotrimer composed of three subunits: α, β, and γ. TFIIAα-β is translated as a single polypeptide and site specifically proteolized by TASP1 into α and β subunits (30). Biochemical studies revealed that cleavage of TFIIAα-β increases susceptibility to proteasome-mediated degradation but does not affect TFIIA’s ability to enhance transcription in vitro (31). Importantly, cleaved and noncleaved TFIIAα-β are equally capable of interacting with the TFIIAγ subunit and with TBP. Recently, we generated a knockin mouse knockin (Tfiianc/nc) that TFIIA proteolysis promotes TFIIA-mediated targeting of TBP-related factor 2 (TRF2) at the spermiogenic gene loci (Tnp and Prm) in a testis-specific manner (32). Consequently, TASP1 noncleavable TFIIAα-β knockin (Tfiianc–/–) mice exhibit male sterility (32).

Here, we report that the TASP1-mediated proteolysis of TFIIAα-β actively represses the transcription of negative cell cycle regulators p16Ink4a and p19Arf, transcribed from the Cdkn2a locus, to enable proper mammalian head development. TASP1 deficiency in mice leads to fatal craniofacial malformations and impaired telencephalic cell proliferation. Noncleaved TFIIAα-β is more stable and accumulates at p16Ink4a and p19Arf promoters. Excessive p16Ink4a and p19Arf transcription and aberrant craniofacial formation result when there is no TASP1 or TASP1 is unable to proteolyze TFIIAα-β. Together, our genetic and biochemical studies establish what we believe to be a novel essential pathway for mammalian head morphogenesis in which transcription of cell cycle regulators (p16Ink4a and p19Arf) is modulated via posttranslational site-specific proteolysis of a general transcription factor, TFIIAα-β.

Results

TASP1 deficiency leads to craniofacial malformations. Our initial study of TASP1-deficient mice on a mixed 129SvJ/C57BL/6 (N2) genetic background revealed that Tasp1+/– pups typically die on P1, without a visible milk spot (19). Skeletal and histological analysis revealed that newborn (P0) Tasp1–/– pups had a shortened skull and a distorted tongue (Supplemental Figure 1, A and B; supplemental material available online with this article; doi:10.1172/JCI77075DS1), which suggests that their demise resulted from suckling defects. Studies in mice deficient for Otx2 or Lim1, two master transcription factors for mammalian head morphogenesis, have shown that the murine C57BL/6 genetic background is associated with greater susceptibility to head malformation (33, 34). Hence, our original line of Tasp1+/– mice was backcrossed to C57BL/6 mice. Interestingly, backcrossing beyond 6 generations

Figure 1.
Prenatal examinations of embryos demonstrated that more than 90% of *Tasp1–/–* embryos at developmental stages E9.5 to E14.5 displayed major craniofacial defects, whereas E8.5 *Tasp1–/–* embryos were indistinguishable from their WT littermates (Figure 2A and Supplemental Figure 2A). The prosencephalons, nasal processes, and first pharyngeal arches of *Tasp1–/–* embryos (E9.5–E10.5) were hypoplastic or absent (Figure 2, A and B). E14.5–E18.5 *Tasp1–/–* embryos exhibited severe underdevelopment or complete absence of the cerebral cortex and striatum as well as absence of the tongue and lower jaw (Figure 2, A and B). Additionally, most *Tasp1–/–* embryos at developmental stages later than E9.5 displayed smaller trunk sizes compared with those of their WT littermates (Figure 2A). Interestingly, this marked reduction in body length distinguishes *Tasp1–/–* deficient animals from mice lacking different head organizer genes, like *Otx2*, *Lim1*, *Ssdpl1*, *Hex1*, *Hex2*, *Hex3*, and *Hex4*.

Figure 2. Disruption of brain architecture in *Tasp1–/–* embryos. (A) Lateral views of representative WT and *Tasp1–/–* embryos at different developmental stages (E8.5–E14.5). *Tasp1–/–* embryos at E9.5 and older show truncations of head structures (93.8% at E9.5, n = 16; 93.0% at E10.5, n = 41; 100% at E12.5, n = 12; 94.3% at E14.5, n = 175). Scale bar: 1.0 mm. (B) Hematoxylin and eosin-stained sagittal sections of WT and *Tasp1–/–* heads at the indicated developmental stages. Skull structures are identified where indicated. Note the hypoplasia of prosencephalic derivatives in *Tasp1–/–* embryos. cp, choroid plexus; cx, cerebral cortex; di, diencephalon; mes, mesencephalon; np, nasal process; oe, olfactory epithelium; os, optic stalk; p, pons; pa, first pharyngeal arch; rh, rhombencephalon; str, striatum; t, tongue; tel, telencephalon. Scale bar: 1.0 mm. (C) Whole-mount anti-CD31 IHC of E10.5 WT and *Tasp1–/–* embryos showing spreading of cranial vessels throughout entire heads. At least 3 embryos were tested for each group. Scale bar: 0.5 mm. (D) Hematoxylin and eosin-stained sagittal sections of WT and *Tasp1–/–* E10.5 embryos. *Tasp1–/–* hearts are smaller but exhibit normal development. at, atrium; ec, endocardial cushion; tr, myocardial trabeculae; vn, ventricle. At least 3 embryos were tested for each group. Scale bar: 0.5 mm. (E) Whole-mount in situ hybridization with *Tasp1* antisense and sense (negative control) probes on E10.5 WT embryos. *Tasp1* mRNA was detected at brain ventricles, pharyngeal arches, and limb buds. At least 3 embryos were tested for each probe. Scale bar: 1.0 mm.

resulted in marked infertility of *Tasp1–/–* males (32). *Tasp1–/–* mice were born from *Tasp1+/–* (N6) intercrosses at near the expected Mendelian ratio, but all died within the first day after birth (Figure 1A). Strikingly, all these C57BL/6 background–enriched *Tasp1–/–* mice displayed arrays of craniofacial malformations, ranging from smaller eyes (microphthalmia), absence of eyes (anophthalmia), absence of lower jaw (agnathia), and rod-like nose (ethmocephaly) to complete absence of head structures anterior to the ears (acephaly) (Figure 1, B and C). In accephalic *Tasp1–/–* pups, the facial bones rostral to the parietal bones were missing or severely deformed, whereas caudal bones, such as the interparietal and suboccipital bones, were present (Figure 1C). On the other hand, we did not observe overt craniofacial defects in the 129SvJ background–enriched *Tasp1–/–* pups from intercrosses of *Tasp1–/–* mice that had been backcrossed to the 129SvJ strain for 6 generations. Prenatal examinations of embryos demonstrated that more than 90% of *Tasp1–/–* embryos at developmental stages E9.5 to E14.5 displayed major craniofacial defects, whereas E8.5 *Tasp1–/–* embryos were indistinguishable from their WT littermates (Figure 2A and Supplemental Figure 2A). The prosencephalons, nasal processes, and first pharyngeal arches of *Tasp1–/–* embryos (E9.5–E10.5) were hypoplastic or absent (Figure 2, A and B). E14.5–E18.5 *Tasp1–/–* embryos exhibited severe underdevelopment or complete absence of the cerebral cortex and striatum as well as absence of the tongue and lower jaw (Figure 2, A and B). Additionally, most *Tasp1–/–* embryos at developmental stages later than E9.5 displayed smaller trunk sizes compared with those of their WT littermates (Figure 2A). Interestingly, this marked reduction in body length distinguishes *Tasp1–/–* deficient animals from mice lacking different head organizer genes, like *Otx2*, *Lim1*, *Ssdpl1*, *Hex1*, *Hex2*, *Hex3*, and *Hex4*. 
and Dkk1-deficient animals (5–7, 34–37). Tasp1-deficient animals have cranial morphogenetic defects, with normal or only slightly smaller body dimensions. Defects in the cardiovascular system can impede expansion of embryonic tissues by limiting distribution of nutrient and oxygen. However, this is unlikely the cause for craniofacial defects in Tasp1−/− embryos, because they exhibited normal development of cranial blood vessels (Figure 2C) and the heart (primitive ventricle, atrium, endocardial cushion, and myocardial trabeculae) (Figure 2D). Furthermore, whole-mount in situ hybridization of E10.5 embryos indicated prominent expression of TASP1 in the brain ventricles, pharyngeal arches, and limb buds (Figure 2E). This distinct pattern of TASP1 expression is consistent with the major phenotypes of Tasp1−/− embryos seen in head and pharyngeal arches.

The telencephalons of Tasp1−/− animals exhibit impaired cell proliferation. Our prior studies using MEFs identified cyclin genes, genes encoding CDKIs, and Hox genes as the key downstream transcriptional effectors regulated by TASP1 through site-specific proteolysis of nuclear factors (19). It is unlikely that the Hox code has any influence on forebrain development, as the cephalic expression boundary of Hox genes is at the rhombomere (38). Thus, we focused on investigating whether a disruption of proliferation accounts for the abnormal development of the Tasp1−/− prosencephalon. In comparison with that in WT embryos, E10.5 Tasp1−/− embryos showed reduced thickness of the telencephalic neuroectoderm, which was composed of 5 to 8 layers of neural progenitor cells, rather than the normal 6 to 10 layers (Figure 3A). Moreover, significantly fewer mitotically active cells were detected in Tasp1−/− telencephalic neuroectoderm (ne) but not in the first pharyngeal arch or the nasal process (n = 3 throughout). Scale bar: 0.2 mm. Error bars represent SD. *P < 0.05, unpaired 2-tailed Student’s t test. (B) Apoptotic cells in the E10.5 prosencephalon were observed by IHC detection of cleaved caspase-3 (arrowheads). The percentage of cleaved caspase-3–positive cells normalized to Hoechst-positive cells did not differ between WT and Tasp1−/− embryos (n = 6 [Tasp1−/−]; n = 5 [WT]). Scale bar: 0.2 mm. Error bars represent SD.

Figure 3. Tasp1 loss results in reduced proliferation in the Tasp1−/− developing forebrain. (A) Immunohistochemical staining for pH3 reveals reduced mitotic growth in the prosencephalic region of E10.5 Tasp1−/− embryos. The percentage of pH3-positive cells normalized to Hoechst-positive cells differed between WT and Tasp1−/− embryos in the telencephalic neuroectoderm (ne) but not in the first pharyngeal arch or the nasal process (n = 3 throughout). Scale bar: 0.2 mm. Error bars represent SD. *P < 0.05, unpaired 2-tailed Student’s t test. (B) Apoptotic cells in the E10.5 prosencephalon were observed by IHC detection of cleaved caspase-3 (arrowheads). The percentage of cleaved caspase-3–positive cells normalized to Hoechst-positive cells did not differ between WT and Tasp1−/− embryos (n = 6 [Tasp1−/−]; n = 5 [WT]). Scale bar: 0.2 mm. Error bars represent SD.
Gene set enrichment analysis (GSEA) of the Molecular Signature Database (C2 canonical pathways) indicates that 4 of the 20 gene sets with the highest normalized enrichment scores are associated with cell proliferation (Figure 4B and Supplemental Table 1). These 4 gene sets contain the negative cell cycle regulators $\text{p21Cip1}$ (also known as $\text{Cdkn1a}$) and $\text{Cdkn2a}$ (Figure 4B). On the other hand, none of the gene sets associated with head development was overrepresented in GSEA. The $\text{Cdkn2a}$ locus encodes 2 distinct proteins from alternative reading frames: $\text{p16Ink4a}$, which is a CDKI, and $\text{p19Arf}$, which promotes p53-dependent apoptosis and cell cycle arrest (39). Quantitative RT-PCR analyses demonstrated that the mRNA levels of...
p16INK4a, p19Arf, and p21Cip1 were 2- to 3-fold higher in Tasp1−/− heads than in WT E10.5 heads (Figure 4C). Expression of Ccne1 and Ccna2, which were previously identified as TASP1-regulated genes in MEFs (19), was only minimally reduced Tasp1−/− heads (Figure 4C).

We further determined the mRNAs levels of head organizer genes, including Otx2, Hex, Hesx1, and Dkk1, and did not detect significantly altered expression in Tasp1−/− E9.5 embryos (Supplemental Figure 2B). Of note, Hex expression was reduced by 25% (Supplemental Figure 2B). Since heterozygous loss of Hex does not induce overt craniofacial aberration (6), the observed Hex reduction is unlikely to account for the drastic malformations of the Tasp1−/− embryo heads. Since MLL1, a substrate of TASP1, was shown to activate expression of MMP1 and MMP3 via interaction with ETS2 transcription factor (40) and remodeling of extracellular matrix is important for tissue morphogenesis, we determined the expression of several MMPs (Supplemental Figure 2C). In Tasp1−/− E10.5 embryos, Mmp3 was reduced. Of note, mice deficient in Mmp3 did not exhibit any craniofacial defects (41). Hence, the Mmp3 reduction is unlikely to account for the overt head defects of Tasp1−/− animals. There were no significant differences in the expression of Mt1-Mmp, which is required for cranial skeleton

---

**Figure 5. Genetic knockin of cleavage-resistant forms of TASP1 substrates reveals that noncleavage of TFIIAα-β phenocopies the craniofacial malformations observed in Tasp1−/− mice.** (A) Mll1nc/nc, Mll2nc/nc, and Mll1nc/nc Mll2nc/nc mice at P0 did not display craniofacial defects. Scale bar: 2.0 mm. (B) WT, Tfiianc/nc, and Tfiia−/− mice obtained from Tfiia+/nc intercrosses were observed at the expected Mendelian ratios at the indicated developmental stages. Nearly 100% of Tfiianc/nc mice died within the first day of birth. (C) Tfiia−/− P0 animals exhibited head malformations similar to those observed in Tasp1−/− animals. Scale bar: 2.0 mm. (D) WT and Tfiia−/− E10.5 and E14.5 embryos with head malformations. Frequencies of the otocephalic phenotypes in E14.5 WT, Tfiia−/−, and Tfiia−/− embryos are shown. Scale bar: 1.0 mm.
development, between WT and Tasp1–/– embryos (Supplemental Figure 2C) (42). Furthermore, Tasp1–/– embryos did not exhibit significant alteration in the expression of Sox1 and Sox2, two key regulators of neuroectoderm (43). Overall, these results suggest that TASP1 is necessary for expansion of the prosencephalon, in part through its restriction of p16Ink4a, p19Arf, and p21Cip1 expression.

To test the hypothesis that cell cycle regulation constitutes the key mechanism by which TASP1 coordinates mammalian cranial morphogenesis, we generated mice deficient in both Tasp1 and Cdkn2a, using Cdkn2a–/– mice, in which both p16Ink4a and p19Arf are deficient, on a pure C57BL/6 background. Remarkably, the deletion of Cdkn2a in our Tasp1–/– Cdkn2a–/– mice significantly rescued the head and body size anomalies of Tasp1–/– mice (Figure 4, C and D). A greater proportion of E14.5 Tasp1–/– Cdkn2a–/– embryos developed a normal head (35.9% in Tasp1–/– Cdkn2a–/– embryos versus 5.7% in Tasp1–/– embryos), and a smaller proportion failed to develop a prosencephalon (5.1% in Tasp1–/– Cdkn2a–/– embryos versus 18.3% in Tasp1–/– embryos) (Figure 4D). To further understand how p16Ink4a and p19Arf contribute to craniofacial development, we generated Tasp1–/– p16Ink4a–/– and Tasp1–/– p19Arf–/– mice, respectively, using p16Ink4a–/– and p19Arf–/– mice on a C57BL/6 background. Deficiency of p16Ink4a reduced the incidence of prosencephalon loss (9.7% in Tasp1–/– p16Ink4a–/– embryos versus 18.3% in Tasp1–/– embryos) (Figure 4D). However, neither p16Ink4a nor p19Arf deficiency alone rescued the gross craniofacial defects of Tasp1–/– mice. Thus, it is likely that suppression of both p16Ink4a and p19Arf during cranial morphogenesis is crucial for normal head development.

Tfiia–/– mice exhibit the same craniofacial malformations as Tasp1–/– mice. In mammals, the bona fide substrates proteolyzed...
by TASP1 are TFIIAα-β, ALFa-β, MLL1, and MLL2. ALFa-β is expressed predominantly in the testes and ovaries (44–46), whereas TFIIAα-β, MLL1, and MLL2 are expressed ubiquitously, including in the head. Hence, we investigated whether TASP1-mediated cleavage of MLL1, MLL2, or TFIIAα-β contributes to head morphogenesis. Mll1nc/nc, Mll2nc/nc, and Mll1nc Mll2nc/nc knockin mice carry homozygous noncleavable mutant Mll1 and/or Mll2 alleles at their native genomic loci (19, 32). None of these mice displayed craniofacial defects on a C57BL/6 background (N10) (Figure 5A). This result is consistent with our previous findings in MEFs that TASP1-mediated cleavage of MLLs regulates cyclin genes but not CDKIs (19). Hence, we generated homozygous Tfiiaα/α mice (32) that were backcrossed with C57BL/6 mice. Like Tasp1–/– pups, Tfiiaα/α pups on the C57BL/6 background–enriched background (N6) were born at the expected Mendelian ratio from Tfiia–/– (N6) intercrosses and succumbed to death within the first day after birth (Figure 5B). Remarkably, Tfiiaα/α and Tasp1–/– mice displayed closely similar otocerebral phenotypes and diminished body sizes at birth (Figure 5C) and during embryogenesis (Figure 5D). Of note, Tfiia is expressed ubiquitously in E10.5 embryos (Supplemental Figure 3A), and thereby, the expression of Tasp1 likely dictates where cleaved TFIIA functions. Notably, none of the Tfiiaα/α mice exhibited acephaly (PO) or prosencephalon loss (E14.5). This result suggests that proteolysis of TFIIAα-β may not be the only way that TASP1 regulates craniofacial development. Therefore, we generated triple mutant Tfiiaα/α Mll1nc/nc Mll2nc/nc animals. However, introduction of Mll1 and Mll2 alleles into Tfiiaα/α mice did not increase the severity of cranial anomalies (Supplemental Figure 3B).

Noncleaved TFIIAα-β is stabilized and targets to the Cdkn2a locus. Thus far, our genetic results demonstrate that (a) Tasp1–/– mice exhibited severe cranial anomalies with disrupted cell proliferation, (b) homozygous loss of Cdkn2a significantly rescued these defects, and (c) Tasp1–/– mice and Tfiiaα/α mice displayed a highly similar spectrum of cranial anomalies. Based on these findings, we hypothesized that TASP1 may promote proper head morphogenesis through the cleavage of TFIIAα-β to prevent undesirable aberrant transcription of p16Ink4a and p19Arf. Accordingly, we investigated whether loss of TASP1-mediated cleavage of TFIIAα-β alters the expression of major cell cycle regulators in Tfiiaα/α heads. Quantitative RT-PCR and immunoblotting revealed upregulation of p16Ink4a, p19Arf, and p21Cip1 but no changes in the mRNA levels of of Cond1, Ccen1, and Cnca2 (Figure 6, A and B), supporting TASP1/TFIIA regulation of p16Ink4a/p19Arf/p21Cip1 as an important regulatory axis in cranial morphogenesis.

Next, we examined how TASP1-mediated cleavage of TFIIAα-β prevents induction of p16Ink4a and p19Arf. Previous studies have shown that noncleaved TFIIAα-β is less susceptible to proteasome-mediated degradation than its cleaved form (31). Consistently, immunoblotting of TFIIA protein in E10.5 Tasp1–/– and Tfiiaα/α heads showed an accumulation of noncleaved TFIIAα-β (Figure 6C). Interestingly, the TFIIAγ subunit of TFIIA also exhibited stabilization in Tasp1–/– and Tfiiaα/α lysates, albeit to a lesser extent than TFIIAα-β (Figure 6C). Notably, TFIIAγ exhibited stabilization in Tasp1–/– and Tfiiaα/α lysates, but not in Tfiiaα/α lysate (Supplemental Figure 3C), suggesting that TFIIAγ is stabilized only when all of the TFIIAα-β stays noncleaved. These results suggest that TASP1-mediated cleavage of TFIIAα-β contributes to the steady-state transcription by regulating TFIIA turnover. Noncleaved TFIIAα-β retains its cleaved form’s ability to bind TBP and is transcriptionally active (30). Accumulation of high levels of noncleaved TFIIAα-β through either cleavage site mutation (Tfiiaα/α) or loss of TASP1 function (Tasp1–/–) should therefore increase the association of TFIIA at the TFIIA target gene loci (Figure 6D). We tested this hypothesis by performing ChIP assays on the heads of E10.5 Tfiiaα/α and WT embryos. Indeed, we observed a significant increase in TFIIA occupancy at p16Ink4a and p19Arf promoters in Tfiiaα/α embryos (Figure 6E).

Discussion

The morphogenesis of the vertebrate head, which is composed of a group of the most elaborate organs in the body, demands a series of dynamic events, coordinating the proliferation, migration, and patterning of different lineages of cells. Brain vesicles, the prosencephalon, mesencephalon, and rhombencephalon, derive from the anterior neuroectoderm (9). Defects in induction of the anterior neuroectoderm in mouse models deficient in Otx2, Lim1, Sdpl, and Hex commonly result in the absence of the prosencephalon by E8.5 and acephaly at PO, if not in prenatal lethality (3–5). In this study, we identified a variety of craniofacial defects in Tasp1–/– pups at PO (Figure 1B). However, Tasp1–/– embryos at E8.5 displayed no overt defects in the prosencephalon (Figure 2A), and acephaly was an uncommon phenotype of PO Tasp1–/– pups (Figure 1C). These observations indicate that TASP1 plays a role in the events subsequent to anterior neuroectoderm induction.

Importantly, the most common phenotype of Tasp1–/– embryos was hypoplasia of the prosencephalon starting at E9.5 (Figure 2, A and B). The prosencephalon serves as a signaling center and a structural support that is critical for the development of craniofacial tissues. For example, the optic vesicle, which develops in the lateral wall of the diencephalon, releases BMP4 and induces the lens placode (47, 48). Sonic hedgehog (Shh) expressed in the ventral prosencephalon is essential for expansion of the frontonasal process that develops into the nose and upper jaw (49, 50). Furthermore, expression of Shh in the anterior foregut endoderm immediately beneath the prosencephalon was shown to be pivotal for the induction of the first pharyngeal arch, which develops into lower jaw (51, 52). Consistently, frequency analysis of the craniofacial defects of Tasp1–/– animals suggested that the shrunken prosencephalon in E10.5 embryos results in anophthalmia or microphthalmia at E14.5 and PO, while prosencephalon loss at E10.5 results in agnathia in addition to eye defects (Figure 1C and Supplemental Figure 2A), suggesting development of eyes is dependent on intact prosencephalon. Histologically, the hypoplastic prosencephalon of E10.5 Tasp1–/– embryos showed reduced thickness of the telencephalic neuroectoderm, overall impaired cell proliferation, and restriction of a few proliferating cells to the ventricular side (Figure 3A). The telencephalic neuroectoderm of E10.5 WT embryos consisted primarily of the ventricular zone (VZ) on the luminal side and the subventricular zone (SVZ) on the surface side. In the VZ, apical neural progenitor cells undergo asymmetric divisions to produce intermediate neural progenitor cells and neurons. Intermediate neural progenitor cells translocate externally to form the SVZ, in which they undergo symmetric divisions (53). The histological features of
**Methods**

**Mice and skeletal studies.** Tasp1<sup>−/−</sup>, Mill<sup>−/−</sup>, Mill<sup>−/−</sup>, and Tfiia<sup>−/−</sup> mice were generated as previously described (19, 32). p16<sup>−/−</sup> and p19<sup>−/−</sup> mice (FVB.129-Cdkn2a<sup>−/−</sup> and B6.129-Cdkn2a<sup>−/−</sup>, respectively) were purchased from the NCI Mouse Repository. Tasp1<sup>−/−</sup>, Tfiia<sup>−/−</sup>, and p16<sup>−/−</sup> mice were backcrossed with C57BL/6J or C57BL/6 mice for 10 generations (N6) and maintained by intercrosses. Mill<sup>−/−</sup> and Mill<sup>−/−</sup> mice were backcrossed with C57BL/6 mice for 10 generations (N6) and maintained by intercrosses. Mill<sup>−/−</sup> and Mill<sup>−/−</sup> mice were backcrossed with C57BL/6 mice for 10 generations (N6) and maintained by intercrosses.

**Embryonic studies.** Tasp1<sup>−/−</sup> mouse heads, possibly reflecting the tissue specificity. In addition to cyclin genes, MLL1 and MLL2 also drive transcription of Hox genes, which regulate specification of the anterior-posterior axis during embryogenesis (38). However, Hox genes seem irrelevant to the craniofacial anomalies caused by TASP1 deficiency, because no Hox genes are expressed anterior to the rhombencephalon, and none of the Hox-deficient mouse models reportedly display craniofacial phenotypes observed in Tasp1<sup>−/−</sup> embryos (Mouse Genome Informatics, http://www.informatics.jax.org). Consistently, Mill<sup>−/−</sup> and Mill<sup>−/−</sup> mice displayed no obvious craniofacial defects, thus we concluded that TASP1-mediated proteolysis of MLL1 and MLL2 is dispensable for normal head development.

In contrast to cyclin genes, how TASP1 controls the transcription of CDKIs has been an open question. Here, we discovered that failure in TASP1-mediated proteolysis of TFIIA<sub>α</sub> in Tfiia<sup>−/−</sup> animals resulted in a robust increase of p16<sup>−/−</sup> and p19<sup>−/−</sup> (Figure 6, A and B), thus demonstrated a signaling cascade that we believe to be novel comprising TASP1 (protease), TFIIA (general transcription factor), and CDKN2A (cell cycle regulators). We displayed in mouse embryos that noncleavage of TFIIA<sub>α</sub> leads to increased protein stability of TFIIA<sub>α</sub> and TFIIA<sub>γ</sub>, consistent with the previous finding in vitro that TASP1-mediated proteolysis of TFIIA<sub>α</sub> accelerates proteasome-mediated degradation (31). Noncleaved TFIIA<sub>α</sub> was shown to interact with TBP and TFIIA<sub>γ</sub> and enhance transcription as efficiently as its cleaved form (31, 58). Consequently, our findings in vivo suggest that the primary function of TASP1-mediated TFIIA proteolysis is the regulation of cellular levels of TFIIA. Our ChIP assays showed that stabilization of TFIIA<sub>α</sub> in Tfiia<sup>−/−</sup> embryos leads to significantly increased TFIIA occupancy on p16<sup>−/−</sup> and p19<sup>−/−</sup> promoters. Accordingly, we concluded that TASP1 cleaves TFIIA<sub>α</sub> to prevent excess recruitment of TFIIA<sub>α</sub> to p16<sup>−/−</sup> and p19<sup>−/−</sup> promoters during mammalian craniofacial morphogenesis. Recently, we elucidated a specific role for TASP1-mediated proteolysis of TFIIA<sub>α</sub> in mammalian spermatogenesis (32). Proteolysis activated TFIIA<sub>α</sub>’s ability to recruit TRF2 for the upregulation of spermiogenic genes (Tnp and Prm) through targeting respective promoters (Supplemental Figure 4), and Tfiia<sup>−/−</sup> mice display immature spermatogenesis in spite of the improved protein stability that noncleavage confers on TFIIA<sub>α</sub> (32). Notably, it is unlikely that recruitment of TRF2 by proteolyzed TFIIA<sub>α</sub> occurs during craniofacial morphogenesis, because the phenotype of TRF2-deficient mice is limited to defects in spermatogenesis. Animals deficient in TRF2 incur neither other embryogenesis defects nor lethality (59). Hence, TASP1 uses various strategies to achieve sophisticated control over diverse biological processes.
MEFs. MEFs were harvested from WT and Tfiia<sup>−/−</sup> E13.5 mouse embryos according to the standard protocol (60). MEFs were cultured in Iscove’s Modified Dulbecco’s Medium supplemented with 20% fetal bovine serum.

**Histology, immunohistochemistry, and cell quantification.** Tissues or whole embryos were collected and fixed in 4% paraformaldehyde (PFA) or Bouin’s solution. Paraffin-embedded sections were sectioned (5–7 μm), rehydrated, and subjected to hematoxylin and eosin staining, immunohistochemistry (IHC), or Hoechst (Invitrogen) staining. For IHC of sections, samples were blotted with the antibody specific to pH3 Ser10 (06-570, Upstate) or cleaved Caspase-3 (9661, Cell Signaling) and visualized with DAB and nickel chloride (Vector Labs). For whole-mount IHC, E10.5 embryos were bleached in 6% H<sub>2</sub>O<sub>2</sub>/methanol and dehydrated in 100% methanol. Samples were blocked in 5% skim milk and 1% Triton X-100 in PBS and incubated with anti-CD31 antibody (557553, BD Pharmingen). Following incubation with peroxidase-conjugated anti-rat IgG, staining was visualized with the DAB Peroxidase Substrate Kit (Vector Labs). Images were acquired with a SPOT camera (Diagnostic Instruments) mounted on an Olympus IX51 microscope (Olympus). Where indicated, cell numbers were determined using the ITCN plug-in for the ImageJ software program and normalized to the number of Hoechst-positive cells.

**In situ hybridization.** Whole-mount in situ hybridization was performed on E10.5 mouse embryos. The cDNAs of mouse Tasp1 and Tfiid<sub>α</sub> were used as the templates to generate RNA probes. Embryos were fixed with 4% PFA in PBS, permeabilized with proteinase K, and then post-fixed with 4% PFA and 0.2% glutaraldehyde in PBS. Hybridization was performed overnight at 65°C with DIG-labeled RNA probes in hybridization buffer (50% formamide, 5x SSC, 0.3 mg/ml yeast RNA, 0.1 mg/ml heparin, 1x Denhardt’s, 0.1% Tween 20, and 5 mM EDTA). Embryos were washed with 50% formamide in 2x SSC, blocked in 1.5% Blocking Reagent (Roche) in KTBT (50 mM Tris-HCl, 140 M NaCl, 10 mM KCl, 0.1% Tween 20), and incubated overnight at 4°C with AP-conjugated anti-DIG Fab fragments (Roche). After extensive washes, the color reaction was carried out using BM purple (Roche).

**RNA isolation, quantitative RT-PCR, and microarray analysis.** For RNA isolation, surgically dissected E10.5 mouse heads (prosencephalons and mesencephalons) were homogenized in TRIzol reagent (Invitrogen) using FastPrep-24 and Lysing Matrix D (MP Biomedicals). cDNA was produced from total RNA extracted using SuperScript II (Invitrogen), oligo-dT (Invitrogen), and random decamer primers (Ambion) according to the manufacturer’s instructions. Quantitative RT-PCR was performed using SYBR Green Master Mix (Applied Biosystems), gene-specific oligonucleotide primers (listed in Supplemental Table 2), and the ViiA7 Real-Time PCR System (Applied Biosystems). Gene expression data were normalized against Gapdh detected using a Gapdh TaqMan probe (Applied Biosystems). For microarray analysis, samples prepared from RNA isolated from E10.5 prosencephalons and mesencephalons were hybridized to GeneChip Mouse ST 1.0 (Affymetrix). The expression signals were subjected to Gene Ontology analysis (Partek) and GSEA (http://www.broadinstitute.org/gsea/index.jsp) to identify overrepresented groups of genes, with common biological processes or pathways. Microarray data were deposited in GEO (accession no. GSE64533).

**Immunoblot analysis.** Dissected E10.5 mouse heads (prosencephalons and mesencephalons) or E13.5 primary MEFs at passage P2 were lysed in RIPA buffer supplemented with complete protease inhibitors (Roche). The mouse head lysates were homogenized for complete dissociation using FastPrep-24 and Lysing Matrix D (MP Biomedicals). Samples were loaded onto NuPAGE gels (Invitrogen) and transferred onto PVDF (Immobilon-P, Millipore). Proteins of interest were blotted with specific antibodies and detected with enhanced chemiluminescence reagents (Western Lightening, Perkin Elmer) and the LAS-300 Imaging System (FUJIFILM Life Science). Antibodies against TASP1 and TFIIAα (SM346) are as previously described (32, 61); antibodies against p16Ink4a (sc74401, Santa Cruz), p19Arf (ab26696, Abcam), TFIIAα (sc5316, Santa Cruz), TBP (sc204, Santa Cruz), and anti–β-actin (AC-15, Sigma-Aldrich) were purchased commercially. See complete unedited blots in the supplemental material.

**ChIP assay.** Tissue was collected from the prosencephalons, mesencephalons, upper jaws, and eyes (but not from the rhombencephalons and lower jaws) of E12.5 mouse embryos; minced with a razor blade; and fixed with 1% PFA. The approximately 10 mg chromatin obtained from 4 × 10<sup>6</sup> to 5 × 10<sup>6</sup> cells was sonicated using a Bioruptor (Diagenode) for 28 minutes to shear the DNA into fragments of 100 to 400 base pairs. Immunoprecipitation was performed using antibodies against TFIIAα (MO431) or rabbit IgG (Sigma-Aldrich) and anti-rabbit IgG Dynabeads (Invitrogen). The anti-TFIIAα antibody was generated by immunizing rabbits against the peptide encompassing aa 1-276 of human TFIIAα-β. Precipitated DNA was assayed by quantitative RT-PCR using gene-specific oligonucleotide primers (listed in Supplemental Table 2). The immunoprecipitation efficiency was determined as the percentage relative to input.

**Statistics.** Results are presented as mean ± SD. Except where otherwise specified, statistical significance was determined by unpaired 2-tailed Student’s <i>t</i> test. A <i>P</i> value of less than 0.05 was considered significant.

**Study approval.** All animal work was performed in accordance to a protocol approved by the Institutional Animal Care and Use Committee of Memorial Sloan-Kettering Cancer Center.
