*J Clin Invest.* 2016;126(6):2367-2371. [https://doi.org/10.1172/JCI84910](https://doi.org/10.1172/JCI84910).

The development of pathologic mucus, which is not readily cleared from the airways, is an important contributor to the morbidity and mortality associated with asthma. It is not clear how the major airway mucins MUC5AC and MUC5B are organized within the mucus gel or how this gel contributes to airway obstruction in asthma. Here, we demonstrated that mucus plugs from individuals with fatal asthma are heterogeneous gels with distinct MUC5AC- and MUC5B-containing domains. Stimulation of cultured human bronchial epithelial cells with IL-13, a key mediator in asthma, induced the formation of heterogeneous mucus gels and dramatically impaired mucociliary transport. Impaired transport was not associated with defects in ciliary function but instead was related to tethering of MUC5AC-containing mucus gel domains to mucus-producing cells in the epithelium. Replacement of tethered mucus with untethered mucus restored mucociliary transport. Together, our results indicate that tethering of MUC5AC-containing domains to the epithelium causes mucostasis and likely represents a major cause of mucus plugging in asthma.

The development of pathologic mucus, which is not readily cleared from the airways, is an important contributor to the morbidity and mortality associated with asthma. It is not clear how the major airway mucins MUC5AC and MUC5B are organized within the mucus gel or how this gel contributes to airway obstruction in asthma. Here, we demonstrated that mucus plugs from individuals with fatal asthma are heterogeneous gels with distinct MUC5AC- and MUC5B-containing domains. Stimulation of cultured human bronchial epithelial cells with IL-13, a key mediator in asthma, induced the formation of heterogeneous mucus gels and dramatically impaired mucociliary transport. Impaired transport was not associated with defects in ciliary function but instead was related to tethering of MUC5AC-containing mucus gel domains to mucus-producing cells in the epithelium. Replacement of tethered mucus with untethered mucus restored mucociliary transport. Together, our results indicate that tethering of MUC5AC-containing domains to the epithelium causes mucostasis and likely represents a major cause of mucus plugging in asthma.

Introduction

Asthma affects approximately 300 million people worldwide and causes approximately 250,000 deaths annually (1). Tracheobronchial mucociliary clearance is impaired in stable asthma (2) and worsens during acute exacerbations (3). The principal cause of death from asthma is asphyxiation from intraluminal airway obstruction by widespread mucus plugs (4–6). In other diseases, mucus transport is impaired due to the absence or immotility of cilia (7), as seen in primary ciliary dyskinesia (PCD), or to periciliary liquid depletion (8) and impaired mucus detachment from submucosal glands (9), as seen in cystic fibrosis (CF). However, the cause of impaired mucus transport in asthma is poorly understood.

The viscoelastic properties of airway mucus depend on 2 gel-forming mucin glycoproteins, MUC5B and MUC5AC (10). MUC5B is produced in submucosal glands and by secretory cells within the airway epithelium (11). MUC5B-deficient mice have impaired mucociliary clearance, leading to pulmonary infections (12). MUC5AC is produced by specialized airway epithelial cells known as mucous (or goblet) cells (11). MUC5AC-deficient mice have normal mucociliary transport and are protected from mucus plugging in an allergic asthma model (12, 13). The type 2 cytokine IL-13 is necessary (14) and sufficient (15) for mucus induction in mouse asthma models. Many individuals with asthma, especially those with high levels of IL-13, have increased MUC5AC mRNA levels but decreased MUC5B mRNA levels (16). Increases in MUC5AC and MUC5B protein concentrations have been reported in sputum from individuals with asthma (17) and in a mucus plug in an individual with fatal asthma (18). We sought to determine whether changes in mucus composition, organization, and function contribute to impaired mucus transport in asthma.

Results and Discussion

MUC5AC and MUC5B localize to distinct domains within mucus plugs in fatal asthma. We compared mucin staining in airway sections from controls and individuals with fatal asthma. In 4 controls, we detected airway epithelial cells containing MUC5AC, MUC5B, or both mucins (Supplemental Figure 1A; supplemental material available online with this article; doi:10.1172/JCI84910DS1) but found no intraluminal mucus (Figure 1, A and B), presumably because intraluminal mucus was removed during standard aqueous-based fixation. In the fatal asthma samples, we detected more MUC5AC- but fewer MUC5B-containing cells (Figure 1, C and D, and Supplemental Figure 1). Large intraluminal mucus plugs were evident in 4 of 7 individuals with fatal asthma (Figure 1, C and D).

Mucin staining within the mucus plugs was heterogeneous: 64% ± 7% (mean ± SEM) of the cross-sectional area of the plugs contained MUC5AC but no detectable MUC5B; 25% ± 5% contained MUC5B but no MUC5AC; and only 11% ± 2% stained for both MUC5AC and MUC5B. MUC5AC and MUC5B therefore localize predominantly to distinct domains within mucus plugs in fatal asthma.

IL-13 induces a heterogeneous mucus gel in vitro. IL-13 is a major driver of asthma in a large subset of individuals and potently induces MUC5AC expression (16). We investigated whether IL-13 stimulation was sufficient to cause changes in mucus gel composition and organization similar to those seen in fatal asthma. IL-13 stimulation of cultured human bronchial epithelial (HBE) cells from multiple individuals consistently increased MUC5AC expression, whereas MUC5B expression was decreased or unaffected (Supplemental Figure 2). We detected numerous MUC5B-containing cells in unstimulated and IL-13–stimulated cultures and a large increase in MUC5AC-containing cells after IL-13 stimulation (Supplemental Figure 3). In rarer cells staining for both mucins, MUC5AC and MUC5B localized to different granules, suggesting discrete secretory pathways and consistent with findings in mice (19).

marked increases in mucus gel solids lead to pronounced periciliary liquid depletion and ciliary collapse (8). The mean concentration of mucus solids from our unstimulated cultures was 1.5% (Supplemental Figure 4C), similar to the 1.7% reported in normal human sputum (20). Mucus solids increased to 2.7% after IL-13 stimulation but remained well below the approximately 7% reported to collapse the periciliary layer and substantially impair mucociliary transport (8). Measurements of ciliary length confirmed that IL-13 stimulation did not cause ciliary collapse (Supplemental Figure 4D). Impaired mucus gel transport in our model system is therefore not explained by loss of multiciliated cells, changes in ciliary beating, or collapse of the periciliary layer.

MUC5AC-containing domains of mucus are tethered to the airway epithelium. We next addressed whether changes in the mucus gel accounted for the impaired transport. In a piglet CF model, loss of the cystic fibrosis transmembrane conductance regulator (CFTR) results in more adherent submucosal gland mucus that remains tethered to gland duct openings, leading to impaired mucociliary transport (9). The pathogenesis of CF is fundamentally different from that of asthma, and the defective mucus transport observed in IL-13–stimulated HBE cells occurred in the absence of submucosal glands. Furthermore, submucosal glands in healthy individuals and individuals with CF produce abundant amounts of MUC5B but no detectable MUC5AC (11), whereas mucus from fatal asthma mucus plugs or IL-13–stimulated HBE cells contained high MUC5AC levels and relatively low MUC5B levels (see above). We hypothesized that MUC5AC-containing mucin domains are tethered to the airway epithelium.

To explore how MUC5AC and MUC5B were organized within extracellular mucus gels, we cultured HBE cells from 3 donors in the absence or presence of IL-13, allowed mucus to accumulate for 3 days, processed the cultures with a nonaqueous fixative, and stained for mucins (2–3 sections, 1 whole-mount preparation per donor). A MUC5B-containing gel was evident in all unstimulated cultures (Figure 1, E and F). MUC5AC staining was not observed but was occasionally seen in other experiments. In contrast, all IL-13–stimulated cultures showed prominent MUC5AC staining and some MUC5B staining (Figure 1, G and H). Gels from IL-13–stimulated cultures were heterogeneous: 59% ± 8% of the cross-sectional area of gels from IL-13–stimulated cultures contained MUC5AC but no detectable MUC5B; 35% ± 8% contained MUC5B but no MUC5AC; and 6% ± 1% stained for both MUC5AC and MUC5B. Hence, IL-13 treatment produced heterogeneous mucus gels with distinct MUC5AC- and MUC5B-containing domains that were similar to those seen in fatal asthma.

IL-13 impairs mucus transport. We determined whether IL-13–induced alterations in mucin composition and organization were associated with changes in the transport properties of the mucus gel by tracking fluorescent microspheres deposited on the gel surface (Figure 2, A and B). Microsphere transport was markedly reduced by IL-13 stimulation (median speed decreased by 21– to 238-fold, Figure 2C). Hence, IL-13 is sufficient to severely impair mucus transport by airway epithelial cells.

Ciliary beating and the periciliary layer are preserved despite impaired mucociliary transport. Ciliary beating propels the mucus gel. The absence of functional multiciliated cells, as seen in PCD (7), or the collapse of the periciliary layer, as seen in CF models (8), leads to impaired mucus gel transport. The IL-13 stimulation conditions we used did not prevent the differentiation of multiciliated cells (Supplemental Figure 4, A and B). Ciliary beat frequency was unaffected by IL-13 (Figure 2D). A previous study showed that

Figure 1. Distinct MUC5AC- and MUC5B-rich domains in mucus from fatal asthma and IL-13–stimulated HBE cells. (A–D) Immunohistochemical staining of mucins in airways from controls (n = 4) and individuals with fatal asthma (n = 7). (E–H) Immunohistochemical staining of sections and whole-mount preparations from 3 unstimulated (– IL-13) or 3 IL-13–stimulated (+ IL-13) HBE cultures. Whole-mount images represent optical sections through the gel (parallel to the plane of the epithelium). epi, epithelium; lum, airway lumen; gel, extracellular mucus gel; filt, filter support. Scale bars: 100 μm (A and C) and 20 μm (B and D–H).

Brief report

Figure 2. IL-13 impairs mucus transport. (A and B) Paths of fluorescent microspheres deposited on gels from unstimulated (-) and IL-13-stimulated (+) HBE cell cultures. The final image from a 10-second image sequence is shown. The trajectories of 5 representative microspheres are indicated by the colored dots. Particles from the unstimulated culture (A) had similar trajectories, whereas particles from the IL-13-stimulated culture had minimal movement (B). Scale bars: 20 μm. (C) Distribution of microsphere velocities for unstimulated and IL-13–stimulated cultures from 3 donors over the 25th to 75th percentile, the line within the box indicates the median, and the whiskers represent minimum and maximum values. The boxes extend from the 25th to 75th percentiles, the line within the box indicates the median, and the whiskers represent minimum and maximum values. (D) Mean ciliary beat frequency was determined from 3 fields; cultures were from 3 individuals. NS compared with unstimulated cultures, by Student’s t test.

Contact between the apical surface of mucous cells and MUC5AC-containing areas of the extracellular gel (Figure 3, B–D, and Supplemental Figure 5). MUC5AC-containing regions of the gel frequently traversed the approximately 6-μm region above the epithelium corresponding to the periciliary layer (Figure 3, A and C). This region was depleted of MUC5B, and MUC5B-containing regions were rarely contiguous with a MUC5B-containing cell (4.7% ± 3.4%). In contrast, MUC5AC-containing regions were frequently continuous with MUC5AC-containing mucous cells (59.4% ± 5.7%; P < 0.01, by Student’s t test). Hence, MUC5AC-containing domains were frequently found in continuity with MUC5AC-producing mucous cells, whereas MUC5B-containing domains were not closely associated with epithelial cells. Similarly, regions of fatal asthma mucus plugs close to the airway epithelium predominantly contained MUC5AC and not MUC5B (Figure 1, C and D, and Supplemental Figure 6).

We directly examined whether MUC5AC-containing domains of the mucous gel were tethered to the epithelial surface by assessing the effects of washing the apical surfaces of HBE cell cultures from 3 donors (3 sections per donor). Unwashed, unstimulated cultures had MUC5B-containing gels (9 of 9 sections, Figure 3E); these gels were not tethered, since no gels were seen after washing unstimulated cultures (0 of 9 sections, Figure 3F). Unwashed, IL-13–stimulated cultures had heterogeneous gels containing distinct MUC5AC-dominant and MUC5B-dominant domains (9 of 9 sections, Figure 3G). After washing, extracellular mucous remained attached to the epithelium (8 of 9 sections, Figure 3H). MUC5AC was present in all 8 washed sections with mucus, but MUC5B was evident in only 3 sections. The ratio of MUC5AC/MUC5B-stained area increased from 2.0 ± 0.3 in unwashed cultures to 6.0 ± 1.1 after washing (P < 0.01, by Student’s t test), indicating preferential attachment of MUC5AC-containing regions. The MUC5B-containing regions seen after washing of IL-13–stimulated cultures were typically associated with MUC5AC-containing regions and were not in direct contact with the epithelium. Hence, MUC5AC-containing regions found in abnormal airway mucus gels are tethered to the epithelium.

Replacement of tethered gels restores mucociliary transport. Mucins are cross-linked by intermolecular disulfide bonds, and addition of the reducing agent DTT to the wash solution led to removal of detectable mucins from IL-13–stimulated as well as unstimulated cultures (Supplemental Figure 7). We analyzed transport in unstimulated and IL-13–stimulated cultures before washing, after washing with DTT, and, finally, after replacement of the gel with a transplanted gel produced by unstimulated donor cells (Figure 3I). Consistent with our previous results, IL-13 markedly reduced the velocity of microspheres prior to removal of the gel. It was recently reported that removal of the mucous gel from healthy airways did not abolish particle transport but instead modestly increased transport velocity (21). We obtained similar results after removal of gels from unstimulated cultures. In comparison, removal of tethered gels from IL-13–stimulated cultures dramatically increased transport to levels that were only modestly lower than those seen in unstimulated cultures. Finally, replacement of the gel with mucus from unstimulated cultures almost normalized transport velocity on IL-13–stimulated cells. These data indicate that mucus transport is restored by replacement of epithelium-tethered MUC5AC-rich gels with untethered gels, demonstrating a mechanism for impaired mucociliary transport that likely plays a significant role in severe asthma.

Mucus hypersecretion is a prominent feature of asthma (22), and this work provides what we believe to be new insights into how changes in mucus contribute to airway obstruction in asthma. An earlier autopsy study demonstrated a large increase in the frequency of airway mucous cells in continuity with intraluminal mucus in individuals with asthma (23).
Many mechanisms contribute to airway dysfunction in asthma. Some factors important in asthma exacerbations, including respiratory viruses and inflammatory cells, were absent in our model and may make independent contributions to impaired mucus transport. Nevertheless, our work shows that IL-13, a key mediator in many individuals with mild-to-moderate (16) and severe asthma (24), is sufficient to produce alterations in the mucus gel that closely resemble those observed in fatal asthma. These alterations result in a MUC5AC-rich gel that is tethered to epithelial mucous cells and markedly impairs mucociliary transport. MUC5AC tethering probably leads to progressive luminal accumulation of mucus and airway plugging. Hence, changes in mucus composition and organization are likely to be major contributors to airway obstruction, morbidity, and mortality in asthma.

**Methods**

Further information can be found in the Supplemental Methods and in Supplemental Figures 1–7.
Statistics. Two-group comparisons were performed using the 2-tailed Student’s t test (normally distributed data) or the Mann-Whitney U test. A P value of less than 0.05 was considered statistically significant.

Study approval. The UCSF Committee on Human Research approved the use of human airway sections and HBE cells. Written consent was not required, as materials were leftover clinical samples obtained from deidentified individuals.

Author contributions
LRB and DJE conceived the study and designed the experiments. LRB, LZ, WF, and DJE performed the experiments and acquired the data. LRB and DJE analyzed and interpreted the results. LRB and DJE wrote the manuscript.
