Adipocytes secrete the hormone leptin to signal the sufficiency of energy stores. Reductions in circulating leptin concentrations reflect a negative energy balance, which augments sympathetic nervous system (SNS) activation in response to metabolically demanding emergencies. This process ensures adequate glucose mobilization despite low energy stores. We report that leptin receptor–expressing neurons (LepRb neurons) in the periaqueductal gray (PAG), the largest population of LepRb neurons in the brain stem, mediate this process. Application of noxious stimuli, which often signal the need to mobilize glucose to support an appropriate response, activated PAG LepRb neurons, which project to and activate parabrachial nucleus (PBN) neurons that control SNS activation and glucose mobilization. Furthermore, activating PAG LepRb neurons increased SNS activity and blood glucose concentrations, while ablating LepRb in PAG neurons augmented glucose mobilization in response to noxious stimuli. Thus, decreased leptin action on PAG LepRb neurons augments the autonomic response to noxious stimuli, ensuring sufficient glucose mobilization during periods of acute demand in the face of diminished energy stores.

Thus, decreased leptin action on PAG LepRb neurons augments the autonomic response to noxious stimuli, ensuring sufficient glucose mobilization during periods of acute demand in the face of diminished energy stores.

Introduction

The hormone leptin, which is produced by adipocytes to signal the repletion of body energy (fat) stores, acts via the leptin receptor (LepRb) on specialized populations of brain neurons to control food intake, energy expenditure, and other metabolic parameters (1–4). The fall in circulating leptin concentrations during negative energy balance increases hunger and initiates an energy-sparing neuroendocrine program characterized by decreased sympathetic nervous system (SNS) tone and diminished activity of the thyroid, reproductive, and growth axes, among others. This response not only tends to replenish body energy stores by increasing feeding relative to energy utilization when food is available, but also preserves remaining energy stores in the face of continued famine, increasing the chances of survival until food becomes available.

The withdrawal of leptin action from LepRb neurons in the hypothalamus mediates most of these orexigenic and energy-sparing responses to negative energy balance (5). While brain stem sites contain many LepRb neurons, roles for most populations of brain stem LepRb neurons, including the largest population (located in the periaqueductal gray [PAG]), remain undefined (6, 7).

In isolation, the energy-sparing neuroendocrine response to negative energy balance carries a potential risk, however. The reduction of energy stores coupled with decreased SNS tone impairs the ability to respond to acute, potentially life-threatening emergencies that require the robust mobilization of metabolic fuels, such as glucose. Thus, during negative energy balance, meeting acutely elevated metabolic needs requires a system that increases the drive to mobilize glucose beyond that which is required when energy reserves are replete. Furthermore, this system must activate specifically in response to metabolic emergencies without otherwise altering SNS tone and glucose mobilization (otherwise, this would blunt the energy-sparing response to negative energy balance). Indeed, we previously defined a system that augments the counterregulatory response (CRR) to hypoglycemia when energy stores are diminished: hypoglycemia activates cholecystokinin-containing (CCK-containing) neurons in the hindbrain parabrachial nucleus (PBN), which project to the ventromedial hypothalamic nucleus (VMN) (which plays a crucial role in the CRR) (8, 9). Some PBN CCK neurons contain LepRb; during negative energy balance, the withdrawal of leptin from these PBN LepRb cells augments their response to low glucose, enhancing glucose mobilization during hypoglycemia without altering baseline endocrine function, energy balance, or glucose homeostasis (8).

We reasoned that other stimuli that signal the need for robust SNS activation and glucose mobilization might similarly engage the PBN→VMN circuit to meet acutely increased metabolic demands when energy stores are low. Because noxious stimuli (such as pain) increase blood glucose and often indicate the need for SNS activation and nutrient mobilization, we sought to understand the potential role for hindbrain LepRb neurons in modulating the response to noxious stimuli in line with the repletion state of body energy stores. We find that LepRb neurons in the PAG (which plays crucial roles in responding to noxious stimuli; refs. 10–13) lie...
upstream of the PBN→VMN circuit. Diminished leptin action on these LepRbPAG neurons augments the hyperglycemic response to noxious stimuli, ensuring appropriately elevated autonomic output to mediate sufficient glucose mobilization in response to acute metabolic need under conditions of negative energy balance.

**Results**

**Noxious stimuli activate LepRb neurons in the PBN and PAG.** Pain and other noxious stimuli activate the SNS and promote the mobilization of metabolic fuels to support the ability to cope with the stimulus-evoking event. Thus, short-term survival when faced with a noxious stimulus during negative energy balance requires a brain system that can overcome low SNS tone and depleted energy stores to support nutrient mobilization. Indeed, a 12-hour fast enhances the hyperglycemic response to the injection of 5% formalin into the footpad of the hind paw (a common noxious stimulus model; refs. 14–16) (Figure 1A).

Since the withdrawal of leptin from leptin-inhibited LepRb neurons in the PBN (LepRbPBN neurons) enhances SNS activation and glucose mobilization during hypoglycemia (8), mitigating the impairment of the CRR that would otherwise occur during negative energy balance, we sought to determine whether the LepRbPBN circuitry might similarly modulate the response to noxious stimuli. We thus examined the potential activation of LepRbPBN cells by noxious stimuli, using the criterion of immunohistochemically detectable c-Fos induction in LepRbGFP-L10a-GFP (LepRbL10a-GFP; ref. 17) mice (Figure 1B), which express an L10a-GFP fusion protein in LepRb neurons, enabling their detection by αGFP immunohistochemistry (Figure 1 and Supplemental Figure 1; supplemental material available online with this article; https://doi.org/10.1172/JCI90147DS1). Indeed, in LepRbGFP-L10a-GFP mice, formalin injection into the footpad promoted c-Fos accumulation in 38% of LepRb PBN neurons (562 ± 23 cells, mean ± SEM; n = 5) (Figure 1, C and D), similar to the effect of glucoprivation by the injection of 2-deoxyglucose (2DG) (which mimics hypoglycemia at the cellular level) on these cells (568 ± 6 cells, mean ± SEM; n = 3) (Figure 1, E and F), suggesting that LepRbPBN neurons might play a role in modulating the response to noxious stimuli, in addition to hypoglycemia, during negative energy balance. Additionally, formalin injection activated approximately 23% of the LepRb neurons (1862 ± 106 cells, mean ± SEM; n = 5) in the neighboring PAG (LepRbPAG neurons) (Figure 1, G and H), although glucoprivation did not activate LepRbPAG cells (Figure 1, I and J).

**Integration of LepRbPAG neurons with the PBN→VMN circuit.** Because noxious stimulus exposure activates both LepRbPBN and LepRbPAG neurons (while glucoprivation activates only LepRbPBN cells), and since the PAG receives and integrates signals related to noxious stimuli, we hypothesized that LepRbPAG neurons might...

mCherry–containing local afferents of PBN-projecting LepRb PAG cells, especially in the PAG. We also observed afferents to the LepRbPAG → PBN circuit in more distant sites, including the dorsal raphe (DR) (Supplemental Figure 3); we observed few afferents elsewhere and none in the spinal cord, suggesting little or no direct input from peripheral nociceptive neurons. Thus, most of the neural signals to the LepRbPAG → PBN circuit enter via other PAG cells.

Since LepRb PAG cells project to the PBN and contain stimulatory neurotransmitters (such as Glu and CCK), activation of LepRbPAG cells should stimulate neurons in the PBN. To test this, we utilized AAV-hMD3q, which mediates the Cre-dependent expression of the Gq-coupled designer receptor exclusively activated by designer drugs (DREADD), permitting the clozapine-N-oxide–stimulated (CNO-stimulated) activation of Cre-expressing neurons in the region where the virus is injected. We injected AAV-hMD3q separately into the PAG or PBN of Lepr Cre mice and examined the induction of c-Fos in these regions following the administration of CNO (Supplemental Figure 4). CNO treatment of PAG-injected mice promoted the accumulation of c-Fos in the PAG and PBN, while CNO promoted robust c-Fos accumulation in the PBN of PBN-injected mice, but little in the PAG. Thus, LepRbPAG neurons lie afferent to and stimulate PBN neurons.

To determine whether PAG neurons, including LepRbPAG cells, lie in direct synaptic contact with the LepRbPAG → VMN circuit, we injected AAV-SynGFP (which mediates the Cre-inducible expression of a synaptophysin-GFP fusion protein to reveal synaptic terminals) into the PAG of LeprCre mice; at the same time, we injected AAV-map2c-dsRed (which mediates the Cre-inducible expression of a map2c-dsRed fusion protein that identifies the dendritic tree) into the PBN of the same mice (Figure 2A). This revealed the projection field of LepRbPAG neurons, which densely innervate the PBN, and demonstrated that many of the synaptic terminals from these cells lie in the PBN region that contains the dendritic tree of LepRbPAG neurons (Figure 2, B and C). We also found terminals from LepRbPAG neurons in the dorsomedial nucleus of the hypothalamus (DMH) and dorsomedial thalamus (Supplemental Figure 2), although these were much sparser than those in the PBN.

We employed rabies-mediated monosynaptic retrograde tracing (18) to examine the circuitry of PBN-projecting LepRbPAG cells. In this system, the injection of the AAV-TVA+G helper virus mediates expression of TVA in Cre-containing neurons to permit their infection by a pseudotyped, G-deleted, mCherry-expressing rabies virus (Rabies-ΔG-mCherry). AAV-TVA+G also mediates the Cre-dependent expression of G, enabling the passage of Rabies-ΔG-mCherry one synapse retrograde to the Cre-expressing neuron. We injected AAV-TVA+G into the PAG of LeprCre/eYFP mice and then delivered Rabies-ΔG-mCherry into the PBN (Figure 2, D–H). This not only infected many LepRbPAG cells with Rabies-ΔG-mCherry (consistent with our identification of the PBN as a major projection target of LepRbPAG cells), but also revealed numerous Rabies-ΔG-mCherry–containing local afferents of PBN-projecting LepRbPAG cells, especially in the PAG. We also observed afferents to the LepRbPAG → PBN circuit in more distant sites, including the dorsal raphe (DR) (Supplemental Figure 3); we observed few afferents elsewhere and none in the spinal cord, suggesting little or no direct input from peripheral nociceptive neurons. Thus, most of the neural signals to the LepRbPAG → PBN circuit enter via other PAG cells.

Since LepRbPAG cells project to the PBN and contain stimulatory neurotransmitters (such as Glu and CCK), activation of LepRbPAG cells should stimulate neurons in the PBN. To test this, we utilized AAV-hMD3q, which mediates the Cre-dependent expression of the Gq-coupled designer receptor exclusively activated by designer drugs (DREADD), permitting the clozapine-N-oxide–stimulated (CNO-stimulated) activation of Cre-expressing neurons in the region where the virus is injected. We injected AAV-hMD3q separately into the PAG or PBN of LeprCre mice and examined the induction of c-Fos in these regions following the administration of CNO (Supplemental Figure 4). CNO treatment of PAG-injected mice promoted the accumulation of c-Fos in the PAG and PBN, while CNO promoted robust c-Fos accumulation in the PBN of PBN-injected mice, but little in the PAG. Thus, LepRbPAG neurons lie afferent to and stimulate PBN neurons.

To determine whether PAG neurons, including LepRbPAG cells, lie in direct synaptic contact with the LepRbPAG → VMN circuit, we injected AAV-TVA+G into the PBN of LepRbPAG mice, followed by the injection of Rabies-ΔG-mCherry into the VMN to mediate the infection of VMN-projecting LepRbPAG (LepRbPAG → VMN) neurons specifically and to label the cells that lie 1 synapse affer-
ent to these cells (Figure 3A). This analysis revealed Rabies-ΔG-mCherry–infected cells in the PBN as well as identifying afferents of LepRb <sup>PAG</sup> neurons in the PAG and in several other nearby areas (Figure 3B). We also observed afferents of LepRb <sup>PBN</sup> neurons in more distal regions, including the DR, the paraventricular nucleus of the hypothalamus, the bed nucleus of the stria terminalis, and the central nucleus of the amygdala (CeA) (Supplemental Figure 5). In addition to demonstrating the expected infection of many GFP-containing LepRb <sup>PBS</sup> cells by intra-VMN Rabies-ΔG-mCherry (Figure 3C), some (<10%) of the PAG neurons afferent to the LepRb <sup>PBN</sup>–VMN cells contained GFP (Figure 3D), revealing that LepRb <sup>PAG</sup> neurons are among the PAG cells that project to and synapse on VMN-projecting LepRb <sup>PBS</sup> cells.

**LepRb <sup>PAG</sup> neurons activate the SNS and increase blood glucose.**

Taken as a whole, our data suggest that LepRb <sup>PAG</sup> cells project to and activate neurons in the PBN→VMN circuit, implying that activating LepRb <sup>PAG</sup> neurons should mimic the CRR, activating VMN neurons in the PBN, and activate neurons in the PBN→VMN circuit, implying that LepRb <sup>PAG</sup> neurons are among the PAG cells that might also participate in other autonomic responses to poten\-tially noxious stimuli that reflect increased metabolic demand, we examined the ventilatory response to hypercapnia in animals expressing hM3Dq in LepRb <sup>PAG</sup> neurons (Figure 4F). CNO administration increased breathing frequency in 3% CO<sub>2</sub>, but not in room air, consistent with augmented SNS drive to respiratory centers. Thus, in addition to increasing SNS outflow to the adrenal gland and elevating blood glucose concentrations, activation of LepRb <sup>PAG</sup> cells augments the ventilatory response to hypercapnia, consistent with a role for these cells in promoting appropriate autonomic responses when metabolic demand is acutely elevated.

Ablation of LepRb from the PAG augments the hyperglycemic and ventilatory responses to noxious stimuli. To determine whether leptin action via brain stem LepRb neurons modulates glucose mobilization in response to noxious stimuli, we evaluated the hyperglycemic responses to noxious stimuli in LepRb <sup>CCK</sup>KO mice (Cck<sup>Cre</sup> Lep<sup>fl/fl</sup>), in which LepRb is ablated from CCK-expressing brain stem neurons (including LepRb <sup>PBS</sup> cells, a substantial number of LepRb <sup>PAG</sup> neurons, and a smaller number of LepRb neurons in the Edinger-Westfall [EW] nucleus) (8) (Figure 5A). As we previously showed (8), the hyperglycemic response to glucopri\-viation is accentuated and prolonged in LepRb<sup>CCK</sup>KO mice (Figure 5B), consistent with the role for LepRb <sup>PBS</sup> neurons in augmenting the CRR to glucoprivation when leptin action is low. Furthermore, LepRb<sup>fl/fl</sup> mice demonstrated an exaggerated hyperglycemic response to formalin injection, revealing that decreased leptin action on LepRb<sup>CCK</sup> neurons augments glucose mobilization in response to noxious stimuli (Figure 5C).

Since leptin action in LepRb<sup>CCK</sup>KO mice is only partially interrupted in the PAG and is also ablated in the EW and PBN (8), we sought to determine the role of PAG leptin action specifically in the response to noxious stimuli. We thus injected AAV-Cre or AAV-mCherry (control) into the PAG of Lep<sup>fl/fl</sup> mice, disrupting LepRb specifically in the PAG (LepRb<sup>PAG</sup>KO mice) to reveal the role of LepRb <sup>PAG</sup> neurons in leptin action (Figure 6A and Supplemental Figure 7). Food intake, body weight, glucose tolerance, insulin-induced hypoglycemia, and the hyperglycemic response to glucoprivation were not altered in LepRb<sup>PAG</sup>KO mice (Figure 6, B–F), consistent with the notion that LepRb <sup>PBN</sup> cells (rather than LepRb <sup>PAG</sup> neurons) augment the CRR to hypoglycemia/glucoprivation when leptin action is decreased.

The hyperglycemic response to formalin injection was significantly enhanced in LepRb<sup>PAG</sup>KO mice, however, revealing that

A constitutive AAV-TetTOX-GFP (which expresses tetanus toxin, preventing neurotransmitter release and effectively silencing all PBN neurons, plus GFP) in mice that also received injections of AAV-hM3Dq in the PBN of LeprCre mice (Figure 7A. As previously, CNO increased blood glucose concentrations in mice expressing hM3Dq in LepRbPAG neurons plus control virus in the PBN (Figure 7, B and C). In contrast, the hyperglycemic effect of CNO was diminished in mice expressing hM3Dq in LepRbPAG neurons plus AAV-TetTOX-GFP in the PBN. Thus, PBN-mediated neurotransmission plays a crucial role in the control of blood glucose by LepRbPAG neurons.

Thus, the withdrawal of leptin action from LepRbPAG cells enhances glucose mobilization and other autonomic responses to noxious stimuli (pain, hypercapnia) that signal acutely increased metabolic demand, consistent with a crucial role for these cells in the brain system that promotes adequate glucose mobilization and SNS activity when metabolic requirements increase acutely during negative energy balance (Figure 7D).

Discussion

We have identified a role for low leptin during negative energy balance in augmenting the autonomic response to noxious stimuli that signify acute unmet metabolic needs, thus ensuring that the drive to mobilize glucose is sufficient to overcome the additive effects of low SNS tone and depleted body energy stores (Figure 1A). Hence, this system can mitigate the detrimental effects of what would otherwise be diminished glucose mobilization during metabolic challenges in the face of the low SNS tone and depleted energy reserves that accompany negative energy balance.

Our findings also reveal the neural circuit that mediates this function (Figure 7D), beginning with LepRbPAG neurons — the largest group of LepRb neurons in the brain stem, whose function was previously unknown (6, 8). Noxious stimuli (which indicate the need to mobilize glucose to support appropriate responses) decreased leptin action on LepRbPAG cells enhances glucose mobilization during noxious stimuli (Figure 6G). Importantly, however, measures of pain perception and sensitivity were not altered in LepRbPAGKO mice (Supplemental Figure 8), indicating that leptin action via the PAG controls glucose mobilization during noxious stimuli, but does not alter the threshold for noxious stimulus perception. Furthermore, the breathing frequency of LepRbPAGKO mice was not different from that of controls in room air, but increased compared with control animals in the presence of 3% CO2 (Figure 6H), consistent with the notion that decreased leptin action on LepRbPAG cells enhances the autonomic hyperventilatory response to hypercapnia.

Our tracing experiments (Figures 2 and 3) suggest that projections from LepRbPAG cells to the PBN could mediate the actions of these cells. To test this directly, we injected control AAV-GFP or a constitutive AAV-TetTOX-GFP (which expresses tetanus toxin, preventing neurotransmitter release and effectively silencing all PBN neurons, plus GFP) in mice that also received injections of AAV-hM3Dq in the PBN of LeprCre mice (Figure 7A. As previously, CNO increased blood glucose concentrations in mice expressing hM3Dq in LepRbPAG neurons plus control virus in the PBN (Figure 7, B and C). In contrast, the hyperglycemic effect of CNO was diminished in mice expressing hM3Dq in LepRbPAG neurons plus AAV-TetTOX-GFP in the PBN. Thus, PBN-mediated neurotransmission plays a crucial role in the control of blood glucose by LepRbPAG neurons.

Thus, the withdrawal of leptin action from LepRbPAG cells enhances glucose mobilization and other autonomic responses to noxious stimuli (pain, hypercapnia) that signal acutely increased metabolic demand, consistent with a crucial role for these cells in the brain system that promotes adequate glucose mobilization and SNS activity when metabolic requirements increase acutely during negative energy balance (Figure 7D).

Discussion

We have identified a role for low leptin during negative energy balance in augmenting the autonomic response to noxious stimuli that signify acute unmet metabolic needs, thus ensuring that the drive to mobilize glucose is sufficient to overcome the additive effects of low SNS tone and depleted body energy stores (Figure 1A). Hence, this system can mitigate the detrimental effects of what would otherwise be diminished glucose mobilization during metabolic challenges in the face of the low SNS tone and depleted energy reserves that accompany negative energy balance.

Our findings also reveal the neural circuit that mediates this function (Figure 7D), beginning with LepRbPAG neurons — the largest group of LepRb neurons in the brain stem, whose function was previously unknown (6, 8). Noxious stimuli (which indicate the need to mobilize glucose to support appropriate responses)
activate LepRbPAG neurons, which project to the PBN→VMN circuit and promote SNS outflow and glucose mobilization. The withdrawal of leptin action from LepRbPAG cells enhances glucose mobilization in response to noxious stimuli, revealing a role for these cells in ensuring adequate glucose mobilization in response to acute demands when leptin levels are low due to negative energy balance. In addition to the obvious survival benefit conferred by this system in the wild, it may also complicate the analysis of glycemic control, especially by inexperienced researchers who inadvertently provoke noxious stimuli while measuring blood glucose in fasted or leptin-deficient animals.

Interestingly, the time course with which the hM3Dq-mediated activation of LepRbPAG neurons augments blood glucose is delayed relative to some acute sympathetic responses to noxious stimuli (such as those that increase heart rate and blood pressure). This finding may indicate that the negative energy balance–mediated augmentation of glucose mobilization in response to noxious stimuli operates via a different, more slowly acting system and thus with a delayed time course compared with these other parameters. This would suggest that LepRbPAG neurons and their circuits play more important roles in response to stimuli that develop over or last for many minutes, thus indicating the need for more sustained glucose mobilization (rather than mediating the immediate response to noxious stimuli that might be adequately met with an initial burst of SNS activation). Alternatively, activation of LepRbPAG neurons or the circuits they subserve might require other contextual cues to mediate the more immediate augmentation of blood glucose.

Since activating LepRbPAG neurons or ablating LepRb in these cells also augments the ventilatory response to hypercapnia (which signals high metabolic demand relative to ventilation), LepRbPAG cells presumably match ventilatory drive to the needs of acutely increased metabolic demand when leptin levels are low. These functions for LepRbPAG cells are consistent with the general role for the PAG in mediating sympathetic activation (23–25) and many autonomic responses to pain (12, 26) as well as the control of respiratory rate and the response to hypercapnia (19–22).

The PAG is a large nucleus, different regions of which play relatively distinct roles in autonomic and behavioral control. The ventral PAG receives projections primarily from the spinal cord and brain stem and mediates passive coping responses, such as freezing and decreasing blood pressure (25, 26). In contrast, the dorsal PAG (especially the caudal dorsal PAG) receives projections from sensory processing centers and mediates active coping responses, such as increased SNS output and flight (23–26). The majority of the PAG LepRb cells lie within this dorsal dorsal region of the PAG, which also contains the vast majority of noxious stimulus–activated LepRb neurons. Due to the size of the PAG, it is not possible to target the entire length and depth of this nucleus by injection; we focused on the caudal dorsal regions with our injections, using 2 injections per side (4 injections total per mouse) to sufficiently target the relevant populations of LepRbPAG neurons. The role of LepRbPAG cells in promoting SNS outflow, activity, glucose mobilization, and increased respiratory rate are consistent with the known output of this region. Since LepRb neurons in other areas of the PAG (and in adjoining structures, such as the DR) could mediate distinct processes, it will be interesting to define their functions as well.

This LepRbPAG→PBN→VMN circuit demonstrates multiple levels of specificity. Since it is engaged by the removal of leptin action, it is activated specifically during negative energy balance, when it is required to augment the drive to mobilize glucose. Also, it is activated only during times of acute need (i.e., it does not augment glucose mobilization in the absence of a noxious stimulus or another inciting event). Furthermore, the overall LepRbPAG→PBN→VMN system is specific for stressors that indicate an acute metabolic challenge (e.g., noxious stimuli, elevated CO2, or in the case of the PBN, glucoprivation); this system is not activated during restraint stress (8) or in response to acute hypertension (data not shown), for instance.

While restraint stress does not activate LepRbPAG or LepRbPEN cells, it activates LepRbPsw cells (27). Since LepRb is ablated from LepRbPsw cells in LepRbCCKKO mice, but the glycemic response to restraint stress is not altered in these animals (8), LepRbPsw cells must modulate different outputs than do LepRbPAG and LepRbPEN cells. Indeed, projections from EW cells target the striatum (28, 29) rather than the VMN, suggesting a potential role for LepRbPsw cells in modulating motivated behaviors, rather than metabolic fuel mobilization.
The output of the LepRbPAG→PBN→VMN circuit is largely specific for the augmentation of SNS outflow: this brain stem circuit does not represent a mechanism by which leptin modulates food intake, body weight, or metabolism at baseline, since none of these parameters were altered in LepRbCCKKO or LepRbPAGKO mice. Furthermore, our data reveal that leptin action on LepRbPAG cells does not alter noxious stimulus perception or responding, since the tail-flick and withdrawal responses are not changed in the LepRbPAGKO mice. This is consistent with our finding that pain-sensing neurons in the spinal cord do not directly synapse on LepRbPAG cells. In addition to noxious stimuli and hypercapnia, it is possible that other signals of acutely elevated metabolic demand that are integrated by the PAG might engage LepRbPAG neurons and their circuitry, as well.

Leptin modulates the LepRbPAG→PBN→VMN circuit at 2 points — the PAG and the PBN. That the circuits downstream of LepRbPAG and LepRbPBN neurons overlap substantially makes teleological sense, since both circuits control similar physiologic end points (SNS outflow and glucose mobilization) and must therefore converge on the same output (the VMN in this case) to mediate their overlapping physiologic functions. This is not dissimilar to the convergence of DMH and arcuate nucleus (ARC) LepRb-expressing neurons on common pathways that control food intake and overall energy expenditure. While on the surface, it may seem redundant for leptin to act at multiple sites within a single circuit, leptin acts at least somewhat distinctly at these 2 sites; PAGLepRb neurons do not contribute to the CRR to hyperglycemia and are only involved in responding to noxious stimuli. Thus, leptin action on LepRbPAG cells does not alter the CRR to hypoglycemia, whereas PBN leptin action does.

The expression of LepRb in the PAG (in addition to the PBN) suggests that PBN LepRb on its own may not adequately augment SNS activation and glucose mobilization in response to noxious stimuli. If so, this could reflect the need for cell-autonomous leptin action to modulate the cellular response to the noxious input. While silencing all PBN neurons blocked the hyperglycemic response...
neither does leptin alter that activity of LepRb PAG neurons in ex vivo slice preparations (data not shown). We previously observed that leptin inhibits LepRb PBN cells under low-glucose conditions (8), but we were unable to detect leptin-mediated inhibition of these cells in normal glucose, suggesting that a relevant activating stimulus might be required to observe the inhibitory effect of leptin on these cells. Hence, the effect of leptin on LepRb PAG neurons might also be detectable only during activation of the neurons by other stimuli (e.g., by pain or hypercapnia). Unfortunately, it is not possible to stimulate ex vivo slice preparations with pain or hypercapnia, since the neurons that initially detect these stimuli lie remote to the LepRbPAG cells. Thus, leptin might inhibit LepRb PAG neurons, but technical issues prevent us from detecting this change in ex vivo slices. Since LepRbPAG neurons are largely glutamatergic (data not shown), the activation of these cells by leptin could also stimulate an inhibitory interneuron to mediate the observed effects. It is also possible that leptin does not directly or acutely alter the firing rate of LepRb PAG neurons, but rather mediates a transcriptional change that alters the magnitude of the response evoked by activating stimuli. Additionally, it is theoretically possible that the PAG could contain multiple subtypes of LepRb neurons.

Despite the power and utility of the genetic tools that we have employed to dissect the function of LepRb PAG neurons, it must be recognized that these manipulations are artificial and extreme; the level of activation, silencing, or degree of leptin insensitivity that these tools produce is unlikely to be recapitulated under physiologic circumstances. Nonetheless, the consistency of the

Figure 7. PAGLepRb neurons act via the PBN to increase blood glucose. (A) Leprcre mice were injected with AAV-hM3dq in the PAG and either a GFP-expressing control virus (n = 7) or AAV-TetTOX-GFP (n = 10) to constitutively express GFP or GFP plus TetTOX in the PBN, respectively. All mice were randomly assigned to receive vehicle control or CNO; mice received the other treatment the following week (B and C). Glycemic responses following vehicle injection were not different between groups and were thus combined into a single control group. (D) Our data demonstrate that PAGLepRb neurons act via the PBN to mobilize glucose and increase adrenal SNA when activated by noxious stimuli such as pain and hypercapnia. In the presence of sufficient energy stores, leptin inhibits these neurons to limit sympathetic activation and hyperglycemia to appropriate levels during the response to noxious stimuli. When energy stores are depleted, however, loss of leptin inhibition of PAGLepRb neurons augments sympathetic and glycemic responses to noxious stimuli to ensure a sufficient glucose mobilization in response to noxious stimuli, despite reduced overall sympathetic tone and the depletion of energy stores. Data are plotted as mean ± SEM; groups with different letters are significantly different. P < 0.05. Data in panel B were analyzed using 2-way repeated-measures ANOVA with Fisher’s LSD post hoc test. Data in panel C were analyzed using 1-way ANOVA with Fisher’s LSD post hoc test.
results produced by the various approaches undertaken suggests the veracity of our conclusions.

In addition to revealing the function of the largest population of LepRb neurons in the brain stem (LepRb<sup>AG</sup> neurons), which had not, to our knowledge, previously been studied, our findings define a new component of the response to fasting and a new physiologic role for leptin: in addition to the hypothalamically mediated energy-sparing neuroendocrine response to starvation, low leptin augments the activation of a LepRb<sup>AG</sup>–PBN→VMN circuit that ensures adequate SNS drive and glucose mobilization to meet the metabolic needs associated with noxious stimuli or hypoglycemia during negative energy balance. In the future, it will be important to identify other stimuli that act via this system to augment SNS outflow during negative energy balance as well as to define the detailed mechanisms by which this circuit mediates glucose mobilization.

**Methods**

**Animals.** All mice were provided with food and water ad libitum unless noted otherwise and kept in a temperature-controlled room on a 12-hour light/12-hour dark cycle. All experiments were carried out using approximately equal numbers of male and female mice. Animals were processed and studied in the order of their randomly assigned ear tags. Investigators were blinded to the genotype and/or treatment for all studies. All mice were genotyped via PCR across the potentially mutated region prior to study. C57BL/6 animals originated from Jackson Laboratories, but all other mice were bred within our colony. LepR<sup>B<sub>Cre</sub>/Cre</sup> mice were on a C57BL/6 background, as previously described (8, 30–32). LepR<sup>B<sub>Cre</sub>GFPLex</sup> mice were generated by interbreeding compound homozygous LepR<sup>B<sub>Cre</sub>CAG-ROSA26LacZ<sub>LacZ</sub>/1.0loxpGFPLex<sub>Lex</sub> mice. LepR<sup>B<sub>Cre</sub></sup> mice were generated by interbreeding compound homozygous LepR<sup>B<sub>Cre</sub>CAG-ROSA26LacZ<sub>LacZ</sub>/1.0loxpGFPLex<sub>Lex</sub> mice. LepR<sup>B<sub>Cre</sub>CAG</sup> KO mice and their controls were generated by breeding male Cck<sup>Cre</sup>/LepR<sup>B<sub>Cre</sub></sup> mice to female LepR<sup>B<sub>Cre</sub></sup> mice. LepR<sup>B<sub>Cre</sub>CAG</sup> mice for AAV-Cre injection were generated by interbreeding homozygous LepR<sup>B<sub>Cre</sub>CAG</sup> mice. When possible, animals were randomly assigned to groups and investigators were blind to treatment.

**Reagents.** The AAV-map2c-dsRed was developed by cloning the coding sequences for the map2c-dsRed fusion protein (in reverse orientation) into the base Cre-inducible AAV vector, using SacI and NheI restriction sites. AAV-map2c-dsRed stocks were prepared at the University of North Carolina (UNC) Vector Core (Chapel Hill, North Carolina, USA). The AAV-Syn-GFP and AAV-TVA+G helper viruses were previously described (33, 34); viral stocks were prepared at the UNC Vector Core. The Rabies-ΔStereotaxic injections. Eight- to fourteen-week-old animals were anesthetized with 1.5%-2% isoflurane in preparation for craniotomy. The skull was exposed, bregma and lambda were leveled, a hole was drilled, and we injected the contents of a pulled pipette at the coordinates of our target for approximately 25 nl/min. For the PBN, 100 nl of virus was injected at anteroposterior (AP) –4.85, mediolateral (ML) ± 1.2, and dorsoventral (DV) –3.3. For the PAG, 100 nl of virus was injected at 4 separate coordinates per animal (AP: –4.9, ML: 0, DV: 0.7); AP: –4.8, ML: ± 0.6, DV: 0.95; AP: –4.7, ML: 0, DV: 0.8). For the VMN, 50 nl was injected at AP: –1.1, ML: ± 0.35, DV: –3.3. After 5 minutes, to allow the virus to diffuse into the brain, the pipette was raised slowly out of the hole in the skull, the hole in the skull was filled with bone wax, and the skin was closed with surgical sutures (Henry Schein). Analgesics were administered prophylactically to all mice to prevent postsurgical pain. The animals were allowed 4 weeks to recover from
surgery before experimental manipulation. At 3 weeks after surgery, the animals were individually housed for experiments that included body weight, food intake, and glycemic analyses. For tracing studies, mice were euthanized at different times after injection depending on the virus (rabies, 1 week; map2c-dsRed/Syn-GFP, 2 weeks). We used fluorescent reporters to confirm injection of the virus into the target brain region in all studies; if the fluorescence was not observed within the region of interest or leaked into another region containing LepRb neurons, these cases were omitted from analyses. In the case of rabies tracing, the VMN injection site was confirmed by visualizing inflammation and the needle track 1 week after injection, since the pseudotyped rabies virus requires TVA expression for initial viral entry and TVA expression was restricted to the PBN.

Adrenal SNA. Adrenal SNA was assessed using multifiber nerve recording. Mice (14 to 20 weeks old) that received the DREADD-hM3dq virus in either the PAG or PBN were initially anesthetized with i.p. administration of ketamine (91 mg/kg body weight) and xylazine (9.1 mg/kg body weight). Intubation with PE-50 was performed to provide an unimpeded airway for the mouse to spontaneously breathe O2-enriched room air. Micro-renathane tubing (MRE-40, Braintree Scientific) was inserted into the right jugular vein for infusion of the sustaining anesthetic agent: α-chloralose (initial dose: 12 mg/kg, then sustaining dose of 6 mg/kg/h). Another MRE-40 tubing was inserted into the left carotid artery for continuous measurement of arterial pressure and heart rate. Core body temperature was maintained at 37.5°C. A retroperitoneal incision was made to gain access to the preganglionic nerve fibers that innervate the left adrenal gland. A single multifiber nerve filament was carefully placed on a bipolar platinum-iridium wire (40 gauge, A-M Systems) and then sealed with silicone gel (Kwik-Sil, WPI). The adrenal nerve signal (AdSNA) was amplified 104 times, with low- and high-frequency filter cutoffs at 100 and 1 KHz, respectively. The amplified and filtered signal was routed to a data acquisition system (MacLab Model 8s), which counted the number of nerve spikes that exceeded a threshold level set just above the noise level each second. After allowing all hemodynamic parameters to stabilize, a slow i.v. infusion of CNO was given over 60 seconds and adrenal SNA was continuously monitored for the next 30 minutes. Next, a slow infusion of vehicle (hydroxypropyl β cyclodextrin; 5 μl/g body weight, i.v.) was given over 60 seconds and the adrenal SNA was continuously measured for next 30 minutes. Background noise was excluded in the assessment of adrenal SNA by correcting for postmortem activity.

Behavioral analyses. Activity of 18- to 22-week-old mice was determined in the open-field test. The mice were introduced to the open-field chamber for 2 hours prior to experimentation. On the following day, the mice were introduced to the chamber for 1 hour of baseline measurement followed by activity recording 1 hour after injection. Data were analyzed as the total number of counts over this 1-hour period. Tail flick and hind paw latency were tested as previously described using a tail-flick test analgesia meter (ITC Life Science) (35). For the tail-flick test, mice were individually restrained during the test to determine the latency to remove the tail away from a 75-degree light on 3 separate instances; the average of the 3 instances was used as an individual data point. For the hind paw test, the mice were allowed to acclimatize to a Plexiglass chamber for 1 hour prior to testing. The 75-degree light was then concentrated on the hind paw of an immobilized mouse, and the latency for the hind paw to move away from the light was recorded (36). As with the tail-flick test, 3 separate instances of this test were recorded and averaged for an individual data point.

Respiratory measurement. Baseline ventilation and the ventilatory response to hypercapnia were measured in freely moving, conscious 14- to 18-week-old mice using a whole-body plethysmograph (Emka Technologies). Gas tanks of O2, N2, and CO2 were connected to the plethysmograph and digitally controlled by the plethysmograph to deliver gas mixtures into each plethysmograph mouse chamber. Each mouse was placed inside the chamber for 20 minutes to acclimate. After acclimation, baseline ventilation was measured while the mice were exposed to room air (e.g., 21% O2, 79% N2, 0% CO2). To determine the ventilatory response to hypercapnia, the CO2 concentration inside the chamber was elevated to 3% for periods of 4 minutes, separated by 5-minute recovery periods in room air (similar to ref. 37), while real-time breathing frequency was recorded. As CO2 was increased, N2 was decreased to allow O2 levels to be stabilized at 21%. In total, mice remained in the plethysmograph for approximately an hour. All respiratory measurements were recorded between 8 am and 1 pm. During recording, mice were continuously monitored by the investigator to ensure that they stayed awake (as the ventilation response is blunted by sleep; ref. 37). If a mouse fell asleep, the investigator aroused the animal by gently tapping on the chamber.

Statistics. Statistical methods were not used to predetermine sample sizes, but our sample sizes are similar to those in previously published studies using similar approaches (8, 17, 37–39). Sample sizes for groups that involved stereotoxic injection of specific populations of cells were 40% larger than for other groups to account for a 50%–60% bilateral hit rate. c-Fos data and activity data were analyzed by 1-tailed t test. Blood glucose data were analyzed by 2-way repeated-measures ANOVA with Fisher’s least significant difference (LSD) post hoc test. Adrenal SNA data were analyzed by 1-tailed t test of 5-minute bins across the experiment. No data were removed unless the injection was a miss or the animal was sick or injured at the time of the experiment (loss of >10% body weight). Data that did not fall under a normal distribution or equal variance were log transformed, then reanalyzed. Significance was set at P ≤ 0.05. All data were analyzed using SigmaStat (Systat).

Study approval. The procedures included in this manuscript were approved by the appropriate Committees on the Use and Care of Animals at the University of Michigan and the University of Iowa.

Author contributions All authors edited the manuscript. JNF designed and contributed to the performance of all experiments, interpreted the data, ran the statistical tests, and wrote the manuscript. MGM also designed all experiments, interpreted the data, and wrote the manuscript. DA and RJS helped design and ran the respiratory measurement testing shown in Figure 4 and Figure 6. WP designed and constructed the AAV-map2c-dsRed used for Figure 2. CP helped design and run the glucose tests shown in Figure 4 and Figure 5. TL contributed to the design and execution of the rabies tracing experiments. PBG aided in studies of PAG LepRb neuron regulation. JS helped run LepRbPAGKO experiments and validation of our mouse models used in Figure 6 and Supplemental Figure 7. MJ helped run PAG and PBN DREADD experiments used for Figure 4. DAM and KR helped design and run adrenal SNA experiments shown in Figure 4. MBA designed and constructed the rabies helper virus.
used in Figure 2 and Figure 3. JH and EF helped design and run pain behavior tests shown in Supplemental Figure 8. DPO helped design and run experiments and helped with data interpretation.

Acknowledgments

We thank MedImmune Inc. for the generous gift of leptin, Karl Deisseroth for the use of AAV-SynGFP, members of the Myers and Olson labs for helpful discussions, and the University of Michigan Vector Core. Research support was provided by the Michigan Diabetes Research Center (NIH P30 DK020572, including the Molecular Genetics, Animal Phenotyping, and Clinical Cores), the American Diabetes Association (to MGM and JNF), the Marilyn H. Vincent Foundation (to MGM), the American Heart Association (to KR), the University of Iowa Center for Hypertension Research and the University of Iowa Fraternal Order of Eagles Diabetes Research Center (to KR), and the NIH (DK098853 to MGM; DK098833 to JNF; HL084207 to KR).
