Mice expressing KrasG12D in hematopoietic multipotent progenitor cells develop neonatal myeloid leukemia

Stefan P. Tarnawsky, …, Rebecca J. Chan, Mervin C. Yoder

Juvenile myelomonocytic leukemia (JMML) is a pediatric myeloproliferative neoplasm that bears distinct characteristics associated with abnormal fetal development. JMML has been extensively modeled in mice expressing the oncogenic KrasG12D mutation. However, these models have struggled to recapitulate the defining features of JMML due to in utero lethality, nonhematopoietic expression, and the pervasive emergence of T cell acute lymphoblastic leukemia. Here, we have developed a model of JMML using mice that express KrasG12D in multipotent progenitor cells (Flt3Cre+ KrasG12D mice). These mice express KrasG12D in utero, are born at normal Mendelian ratios, develop hepatosplenomegaly, anemia, and thrombocytopenia, and succumb to a rapidly progressing and fully penetrant neonatal myeloid disease. Mutant mice have altered hematopoietic stem and progenitor cell populations in the BM and spleen that are hypersensitive to granulocyte macrophage–CSF due to hyperactive RAS/ERK signaling. Biased differentiation in these progenitors results in an expansion of neutrophils and DCs and a concomitant decrease in T lymphocytes. Flt3Cre+ KrasG12D fetal liver hematopoietic progenitors give rise to a myeloid disease upon transplantation. In summary, we describe a KrasG12D mouse model that reproducibly develops JMML-like disease. This model will prove useful for preclinical drug studies and for elucidating the developmental origins of pediatric neoplasms.

Mice expressing Kras<sup>G12D</sup> in hematopoietic multipotent progenitor cells develop neonatal myeloid leukemia

Stefan P. Tarnawsky, Michihiro Kobayashi, Rebecca J. Chan, and Mervin C. Yoder

Introduction
Juvenile myelomonocytic leukemia (JMML) is a pediatric myeloproliferative neoplasm (MPN) caused by somatic mutations in the RAS/MEK/ERK pathway signaling genes, including KRAS, NRAS, PTEN, NF1, and c-CBL (1). These mutations result in a hypersensitivity of hematopoietic progenitors to granulocyte macrophage-CSF (GM-CSF) and lead to monocytosis, anemia, thrombocytopenia, hepatosplenomegaly, and infiltration of peripheral tissues with histiocytes (2–4). Compared with other pediatric hematologic malignancies, the prognosis of patients with JMML is very poor. Allogeneic hematopoietic stem cell (HSC) transplantation is the only curative therapy, which nonetheless has a 5-year overall survival rate of only 52% (5).

The majority of JMML cases result from a mutation in a single gene (6–8). As such, disease models using the most common JMML-initiating mutations have been readily generated (9–11). The MxiCre Kras<sup>G12D</sup> mouse was the first conditional animal model of JMML and continues to be studied extensively (12, 13). However, these mice succumb with MPN that can be exacerbated by T cell leukemia/lymphoma (T-ALL) and that is confounded by non-hematopoietic Kras<sup>G12D</sup> expression (14–18). While the use of inducible MxiCre serves to limit oncogene expression until after birth, nonhematopoietic expression, and the pervasive emergence of T cell acute lymphoblastic leukemia. Here, we have developed a model of JMML using mice that express Kras<sup>G12D</sup> in multipotent progenitor cells (Flt3Cre<sup>+</sup> Kras<sup>G12D</sup> mice). These mice express Kras<sup>G12D</sup> in utero, are born at normal Mendelian ratios, develop hepatosplenomegaly, anemia, and thrombocytopenia, and succumb to a rapidly progressing and fully penetrant neonatal myeloid disease. Mutant mice have altered hematopoietic stem and progenitor cell populations in the BM and spleen that are hypersensitive to granulocyte macrophage-CSF due to hyperactive RAS/ERK signaling. Biased differentiation in these progenitors results in an expansion of neutrophils and DCs and a concomitant decrease in T lymphocytes. Flt3Cre<sup>+</sup> Kras<sup>G12D</sup> fetal liver hematopoietic progenitors give rise to a myeloid disease upon transplantation. In summary, we describe a Kras<sup>G12D</sup> mouse model that reproducibly develops JMML-like disease. This model will prove useful for preclinical drug studies and for elucidating the developmental origins of pediatric neoplasms.
progenitors from Flt3Cre+ KrasG12D mice demonstrated hyper-sensitivity to GM-CSF in colony-forming assays, which was corrected by MEK inhibition (Figure 1E and Supplemental Figure 6). To confirm that the disease in Flt3Cre + KrasG12D animals was initiated in utero and could be propagated autonomously in vivo, we transplanted E14.5 fetal liver (FL) cells into adult BoyJ animals (Figure 2A). Progenitors from mutant donors showed robust engraftment and rapidly contributed to monocytosis, anemia, and thrombocytopenia (Figure 2, B and C, and Supplemental Figure 7). Mutant progenitors gave rise to expanded myeloid cell populations in the BM and spleen, leading to hepatosplenomegaly and a median survival of 9 weeks (Figure 2, D–H). In stark contrast to other KrasG12D models, primary recipients of Flt3Cre+ KrasG12D progenitors showed no signs of T-ALL (Figure 2I). Upon secondary transplantation with 4 × 10^6 primary BM cells, Flt3Cre + KrasG12D mutant cells engrafted, and 5 of 6 recipients rapidly succumbed with monocytosis, splenomegaly, and thymic atrophy (Supplemental Figure 8). These findings indicate that temporal expression of KrasG12D in utero transforms fetal hematopoietic progenitors into transplantable JMML-initiating cells.

We proceeded to analyze the effect of fetal KrasG12D expression on the frequency and distribution of HSCs and progenitors. In contrast to Mx1Cre+ KrasG12D animals (16), we observed a reduction of HSCs (Tomato+ LSK CD150+CD48–) and MPPs (GFP+ LSK CD150–CD48+) in both the BM and spleen of moribund Flt3Cre + KrasG12D mice (Figure 3A). This reduction corresponded with increased quiescence among HSCs in Flt3Cre+ KrasG12D mice (Figure 3B and Supplemental Figure 9). These effects were mediated non–cell autonomously, since LSL-KrasG12D was not recombined in HSCs (Supplemental Figure 10). We proceeded to analyze the progeny of Flt3Cre+ KrasG12D progenitors and found that BM cells cultured in cytokine-free medium gave rise to histiocytes that expressed CD11c and that natal MPN when expressed in fetal hematopoietic progenitors using Flt3Cre and have thereby defined the crucial cellular and developmental environment needed to produce authentic features of KrasG12D-induced JMML.

Results and Discussion
We mated Flt3Cre+ ROSA^mTmG/mTmG studs with dams bearing a conditional Lox-STOP-Lox Kras G12D/+ allele (LSL-KrasG12D/+) to generate Flt3Cre+ ROSA^mTmG/+ LSL-KrasG12D/+ mice (hereafter referred to as Flt3Cre+ KrasG12D mice), in which oncogene expression could be monitored by a switch from Tomato to GFP expression. Flt3Cre+ KrasG12D mutants were born at expected Mendelian ratios and had weight gain comparable to that of their littermates until 2 weeks of age (Figure 1A and Supplemental Figure 1A; supplemental material available online with this article; https://doi.org/10.1172/JCI94031DS1). Mutants and littermates had equivalent activity of Flt3Cre, as measured by the percentage of GFP+ cells, and LSL-KrasG12D recombination in mutant mice was confirmed by PCR (Supplemental Figure 1, B and C). After 2 weeks, Flt3Cre+ KrasG12D mice showed progressive weight loss, leukocytosis, anemia, thrombocytopenia, and hepatosplenomegaly and died at a median age of 26 days (Figure 1, A–C, Supplemental Figure 2, and Supplemental Figure 3). Histological organ examination revealed a histiocytic infiltrate in the spleen, liver, lung, and intestines (Supplemental Figure 4), and a markedly increased frequency of CD11b+Gr1+ cells in the BM, blood, liver, and spleen was confirmed by flow cytometry (Figure 1D and Supplemental Figure 5). Notably, the frequency of CD3+ T lymphocytes and B220+ B lymphocytes was decreased, and Flt3Cre+ KrasG12D mice had an atrophied thymus compared with that seen in the littermates (Figure 1D, Supplemental Figure 3, and Supplemental Figure 4C). Consistent with a faithful model of hyperactive RAS-induced JMML, BM progenitors from Flt3Cre+ KrasG12D animals demonstrated hyper-sensitivity to GM-CSF in colony-forming assays, which was corrected by MEK inhibition (Figure 1E and Supplemental Figure 6).

To confirm that the disease in Flt3Cre+ KrasG12D animals was initiated in utero and could be propagated autonomously in vivo, we transplanted E14.5 fetal liver (FL) cells into adult BoyJ animals (Figure 2A). Progenitors from mutant donors showed robust engraftment and rapidly contributed to monocytosis, anemia, and thrombocytopenia (Figure 2, B and C, and Supplemental Figure 7). Mutant progenitors gave rise to expanded myeloid cell populations in the BM and spleen, leading to hepatosplenomegaly and a median survival of 9 weeks (Figure 2, D–H). In stark contrast to other KrasG12D models, primary recipients of Flt3Cre+ KrasG12D progenitors showed no signs of T-ALL (Figure 2I). Upon secondary transplantation with 4 × 10^6 primary BM cells, Flt3Cre+ KrasG12D mutant cells engrafted, and 5 of 6 recipients rapidly succumbed with monocytosis, splenomegaly, and thymic atrophy (Supplemental Figure 8). These findings indicate that temporal expression of KrasG12D in utero transforms fetal hematopoietic progenitors into transplantable JMML-initiating cells.

We proceeded to analyze the effect of fetal KrasG12D expression on the frequency and distribution of HSCs and progenitors. In contrast to Mx1Cre+ KrasG12D animals (16), we observed a reduction of HSCs (Tomato+ LSK CD150+CD48–) and MPPs (GFP+ LSK CD150–CD48+) in both the BM and spleen of moribund Flt3Cre+ KrasG12D mice (Figure 3A). This reduction corresponded with increased quiescence among HSCs in Flt3Cre+ KrasG12D mice (Figure 3B and Supplemental Figure 9). These effects were mediated non–cell autonomously, since LSL-KrasG12D was not recombined in HSCs (Supplemental Figure 10). We proceeded to analyze the progeny of Flt3Cre+ KrasG12D progenitors and found that BM cells cultured in cytokine-free medium gave rise to histiocytes that expressed CD11c.
enhanced myeloid cell production compared with adult progenitors targeted by Mx1Cre (24, 27). This context emulates studies of JMML patients that highlighted the fetal origins of this disease: the causative somatic mutation commonly occurs before birth, and BM cells have a gene expression signature that is characteristic of fetal progenitors (22, 23). Therefore, in contrast to Mx1Cre, Flt3Cre targets KrasG12D expression to hematopoietic progenitors at the appropriate developmental stage to recapitulate the origin of JMML.

The identity of the JMML-initiating cell has been controversial. On the one hand, case reports have shown that CD34+CD38– phenotypic HSCs express disease-initiating mutations (6, 35) and that xenotransplantation of patients’ progenitors gives rise to mutated myeloid, B, and T cells with a common clonal origin (36). On the other hand, circulating T lymphocytes from most patients do not express the disease-initiating mutation (7, 37), suggesting that JMML is initiated within a MPP that undergoes a differentiation block during T lymphocyte commitment. Consistent with this hypothesis, case reports suggest that patients with JMML have decreased T cell frequencies in the BM and spleen (38, 39). These findings parallel our Flt3Cre+ KrasG12D model, which has a paucity of T cells, an atrophied thymus, and abnormal T cell differentiation.

An earlier study found similarly skewed T lymphocyte development when KrasG12D expression was restricted to DCs in p53−/− mice (40). Our results advance these findings to show that KrasG12D expression in multipotent progenitors results in widespread tissue infiltration with DCs that are distinct from the concomitantly and CD135 (Supplemental Figure 11). This finding is reminiscent of reports describing DC-like tumor cells in patients with JMML (2, 33, 34) and prompted us to analyze DC populations in Flt3Cre+ KrasG12D animals. We observed a marked increase in the frequency of CD11c+ cells in the BM and spleen (Figure 3C). Strikingly, the CD11c+ cell expansion was particularly prominent in the atrophied thymus, where we saw a concomitant deficit of CD4+CD8− committed T cell progenitors and CD4+CD8− double-positive cells (Figure 3, C–F, and Supplemental Figure 12). We also observed this propensity for preferential DC differentiation in recipients of Flt3Cre+ KrasG12D FL progenitors (Supplemental Figure 13).

We present the first KrasG12D model to our knowledge to unify JMML disease-defining features: an in utero origin; viability at birth followed by a failure to thrive; anemia; thrombocytopenia; monocytosis; hepatosplenomegaly; and infiltration of tissues with histiocytes. All Flt3Cre+ KrasG12D mice succumbed to a myeloid disease that could be recapitulated following FL transplantation. This is in contrast to existing KrasG12D models, whose MPN is exacerbated by nonhematopoietic oncogene expression and by the unpredictable coemergence of T-ALL (15–20).

Flt3Cre has an expression pattern markedly different from that of Mx1Cre, which may explain the observed respective myeloid versus lymphoid disease outcomes. Mx1Cre is used to target adult progenitors, whereas Flt3Cre becomes active in fetal MPPs. As such, Flt3Cre initiates KrasG12D expression within an in utero progenitor that is more proliferative, has greater repopulating ability, and has overall survival following transplantation (statistical analysis by Mantel-Cox test). (G–I) Normalized tissue weights of analyzed animals. *P < 0.05, **P < 0.01, and ***P < 0.001, by unpaired, 2-tailed Student’s t test (B–E and G–I).
lates underappreciated features of JMML such as a paucity of mature T lymphocytes and an expansion of DCs and thereby hints at potential new therapeutic strategies. Flt3Cre+ KrasG12D mice will prove useful for preclinical drug studies targeting the RAS/MEK/ERK signaling pathway and will help elucidate the developmental origins of JMML and pediatric leukemias.

**Methods**

Detailed methods, including all flow cytometry antibodies (Supplemental Table 1), are described in the Supplemental Methods.

**Study approval.** Animal studies were approved by the IACUC of the Indiana University School of Medicine. Animals were genotyped using primers outlined in Supplemental Table 2 of Supplemental Methods.

**Statistics.** P values comparing mutant and littermate groups were calculated using 2-tailed Student’s t tests, Mantel-Cox log-rank tests, or χ² tests, as indicated in the figure legends. P values of less than 0.05 were considered significant. All error bars represent the SEM.

**Author contributions**

SPT conceived the study, designed, performed, and analyzed experiments, and wrote the manuscript. MK designed and performed experiments. RJC and MCY conceived the study, designed and analyzed experiments, and wrote the manuscript.

**Acknowledgments**
